## ENCYCLOPEDIA OF MODERN CORAL REEFS – STRUCTURE, FORM AND PROCESS

### Volume Editor

David Hopley is Professor Emeritus in the School of Earth and Environmental Science at James Cook University, Townsville, Queensland, Australia, where he has worked since 1965. He has an M.A. from the University of Manchester and Ph.D. from James Cook University. His initial research into Holocene sea levels and tropical landforms quickly focused on the evolution of coral reefs, reflecting the importance of the Great Barrier Reef to his home institution. Experience with coral reefs extends to many parts of the world including Australia, Barbados, India, Indonesia, Maldives, Papua New Guinea, Rodrigues and Thailand. He has authored and edited almost 200 scientific publications. Amongst numerous awards have been the J.P. Thomson silver medal from the Royal Geographical Society of Australasia (1984) and Life Membership of PACON International (1992).

### Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published, so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the dustjacket of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to <http://www.springerlink.com/reference-works/> to visit the "Earth Sciences Series" online.

### About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the *Encyclopedia of Earth Sciences Series*. For the past 25 years, he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Research Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia, the Caribbean, South America, southwest Pacific islands, southern Africa, Western Europe, and the Pacific Northwest, Midwest, and Southeast USA.

### Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 encyclopedias in the Earth Sciences Series. During his career, he has worked as a petroleum geologist in the Middle East and been a World War II intelligence officer in the southwest Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil, and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

## Dedication to Rhodes Fairbridge (21st May 1914 to 8th November 2006)

A tribute to Rhodes W. Fairbridge in this Encyclopedia of Modern Coral Reefs could not be more appropriate. He was the founding editor of the *Encyclopedia of Earth Sciences Series*, launched in 1966 and continued as Series Editor and for a number of volumes, as Editor-in-Chief, until he passed away in 2006. The series consists of almost 30 volumes and reflects Rhodes' holistic knowledge of the earth, ocean and atmospheric sciences.

Although Rhodes spent his career at Columbia University in New York, he was born in Pinjarra, Western Australia. He graduated with degrees in geology from Queens University, Canada and Oxford University U.K. before receiving a DSc. from the University of Western Australia in 1942. During the war he served in the Royal Australian Air Force where, with friend and colleague Curt Teichert he became interested in aerial photography of coral reefs, initially from a military point of view but subsequently as an aid to interpreting the surficial features of reefs, his first study site being Low Isles on the Great Barrier Reef, the location of the 1928-29 Royal Society Expedition led by Sir Maurice Yonge.

From this time on Rhodes' research interests, to 1955 at the University of Western Australia, then at Columbia University, New York were intimately related to the topics around which this encyclopedia revolves. His interests in coastal geomorphology and especially in past sea level features were promoted by the spectacular calcarenite coastline of south-western Australia. Features of climate change are also prominent in arid climates, such as most of Western Australia, and this too became a focus of Rhodes' interests.

It is not surprising that Rhodes took a very active interest in the newly developing techniques of radiometric dating. In particular they allowed for the quantification of Quaternary events, particularly sea level change. He was the first to put together a sea level curve for the Holocene

and, although developed from different locations and not applicable to all sites, the Fairbridge sea level curve did much to promote coastal studies. This was no more so than at the 1969 Paris INQUA meeting where the gathering of the Sea Level Commission and the associated field excursion around the Atlantic coast of France saw the emergence of numerous ideas which were developed over the next few decades and applied to the many areas from where the INQUA delegates had come.

Rhodes was a scientist with extremely wide vision with a natural curiosity which saw him following up explanations across different fields of science. Sea level change led him into oceanography and climate change which he examined at a broad geological timescale. He was ahead of his time in accepting the Milankovitch theory directing his interests into the planetary sciences. When global climate change became a focus of discussion no-one was in a better position than Rhodes to put some of the initial ideas into a more reasonable context pointing out that the earth's climate has always been changing and that data was needed to evaluate human contribution to global warming. Again he was predicting the future direction of research although his conclusion that "Whatever the present trend, the last word will always be political", seems especially prognostic!

The ideas of Rhodes Fairbridge permeate through this encyclopedia which I believe is a most appropriate volume to pay tribute to his contributions to science in general and to the Earth Sciences Encyclopedia Series in particular. I am especially honoured to be able to make this dedication as Rhodes, who always retained his Australian citizenship, had a strong influence on the early part of my career. My honours and Masters theses were on the coast of North Wales and reference to Rhodes' sea level work was inevitable and even more so for my 1970 PhD. on the coast and islands of North Queensland. However, by

Field trip on the coast of northern France at the 1969 INQUA conference (left David Hopley, right Rhodes Fairbridge)

that time I had not only met Rhodes (initially when he passed through Townsville) but had spent more than 3 weeks with him on the second half of his expedition to the islands east of New Guinea (Misima, Rossell and Louisiades etc.). He had recognised that my experience with reefs (coming from the UK) was minimal and saw

this as an ideal opportunity for “field tutoring”. It certainly paved my way into reef research. Also on the expedition was Rhodes’ charming wife Dolores (then working for the Carnegie Museum) who did much to lighten what at times were some very dark days (including the edge of a tropical cyclone). This included suggesting that whilst at sea, the men of the expedition wear lap-laps!

More time was spent with Rhodes a few months later at the 1969 Paris INQUA meeting. We were also together on the field trip around the French coast from Sangatte to Les Sables d’Olonne, where I think Rhodes’ breadth of knowledge and respect from fellow Quaternary scientists really shone through. Subsequently, apart from a couple of days with Rhodes and Dolores at their Long Island home at Amagansett, contact for me unfortunately has only been through occasional sea level meetings and committees.

Rhodes Fairbridge has left many testaments by which he will be remembered. None, I believe, are more appropriate than the *Encyclopedia of Earth Sciences Series*. However, it is a privilege to have this dedication to such a prominent twentieth century ‘Man of Science’ especially in this specific encyclopedia on coral reefs.

David Hopley  
Editor-in-Chief

## Preface

From navigational hazards in the seventeenth and eighteenth centuries to enigmatic scientific features in the nineteenth century, coral reefs over the last 100 years have not only been understood in greater detail but also have provided evidence of macroscale geological processes such as plate tectonics. Charles Darwin's 1842 book based on his 1831–1836 circum global voyage of exploration on HMS *Beagle* strongly focused the interests of science on coral reefs. Interestingly, his ideas of subsid-ing foundations were developed whilst in South America and before he had seen a coral reef in the field. However, his work promoted both supportive hypotheses and alternatives which included ideas on glacial sea-level control, antecedent platforms, and other ideas which were very much more divorced from field observation than those of Darwin himself, who, in the fourth chapter of his book develops the biological aspects of his theory and the various conditions under which corals can grow.

The ideas, together with his oft quoted wish,

that some doubly rich millionaire would take into his head to have borings made in some of the Pacific and Indian atolls, and bring home cores for slicing from a depth of 500 or 600 feet

were a forecast of the way coral reef research would travel in the twentieth century. Although many hypotheses have been applied to all scales of reefal features and processes, hypotheses testing is now expected, and with this has come the development of research tools such as survey techniques like aerial photography and satellite imagery. The first views of coral reefs from the sky opened up whole new dimensions and directly aided the field-based study of coral reefs, to the same extent that the laboratory analysis such as palaeoenvironmental reconstruction, has in more recent times.

The understanding of how small polyps can construct enormous coral reefs more than 100 km<sup>2</sup> is of central interest to earth scientists but is just as much the area of many other fields of science. The breakdown of

boundaries around the traditional fields of science is a developing theme of the twenty-first century and is no more so than in the study of coral reefs. Corals were initially thought to be plants until the work of André de Peyssonnel (1727) although it took another 24 years for the Royal Society of London to accept them as animals. Coral reefs are the largest structures on earth built by a combination of plants and animals and inevitably they have become the major focus of research for zoologists, botanists, and ecologists. It is impossible to study reefs without input of ideas from these disciplines. However, almost every facet of earth science – geology, geography, geomorphology, sedimentology, oceanography, palaeontology, tectonics, etc. – contributes to the understanding of coral reefs and is included in this encyclopedia. The purpose of the encyclopedia is to promote interdisciplinary research and to help in the communication between earth science and other disciplines by providing a window onto the approaches of earth science to coral reefs and giving other disciplines an understanding of the way corals are viewed by the earth science community. As editor of this volume, I see any way that brings the diverse range of disciplines closer together and understanding each other's knowledge as highly productive. However, it is hoped that within the volume there will also be much to help other earth scientists. Every attempt has been made to make the entries as authoritative and up-to-date as possible with latest reference lists and a range of cross-references which will help in the navigation of this volume.

Why the title – *Encyclopedia of Modern Coral Reefs – Structure, Form and Process*? Again, to some extent, it is to make it attractive to multidisciplinary readers. “Cainozoic” or “Quaternary” could have been used but the technical terms may have made it less attractive to other disciplines. Also, modern coral reefs have a continuous lineage with the earliest Palaeozoic reefs, hence the few entries which cover earlier reefs and their influence on today's living reefs in the volume. Structure,

form, and process are the essential ingredients in the earth science recipe for understanding coral reefs as well as most other landforms.

During the last 100 years, coral reefs have attained new values beyond the support of local subsistence economies. They have provided sites for navigational aids and in days of aircraft with limited range, stopover refuelling sites. During World War II many mid-oceanic atolls had strategic importance and following the war, some became testing sites for nuclear weapons. Ironically, the drilling associated with this testing did much to extend the knowledge of the origin of reefs and in particular, support Charles Darwin. Reefs are important sites for commercial as well as subsistence fishing, and further economic value has been added by tourism.

Unfortunately, the future for coral reefs is very uncertain. They are one of the ecosystems most at risk from global climate change and because of this have achieved much prominence in recent times. They have been compared to canaries in coal mines, providing early warning of increasing risks! Both public and scientific perspectives on the impacts of global warming on coral reefs have changed over the last 20 years. Initially a rise in sea level was seen as positive, encouraging new coral growth over largely dead reef flats, although at the other extreme were forecasts of reefs being drowned, all reef islands disappearing and even the reefs themselves being eroded away and tropical coastlines losing their protection. More balanced responses have come as scientists working on processes opened up a range of possibilities. Earth science has played a major role in these revisions especially where cooperation with other disciplines has provided balanced assessments. Impacts will be severe with bleaching from temperature rise and calcification rates declining in response to acidified oceans, leading to unsustainable growth rates of corals and many other important organisms. The earth science focus here is on the impact on sediment budgets and the transportational ability of waves. Many scenarios are possible including an increase in available sediment over the reef top, and, with deeper water greater ability of waves to move both this new sediment and that which may have rested on the reef top for several thousand years, towards any preexisting reef island. At least in the foreseeable future, the actual volume of reef islands may increase, though new areas added will lack vegetation and soils and may be at the expense of the areas which have supported subsistence agriculture for millennia.

What is becoming more apparent, as further research into the impact of climate change on reefs is carried out, is that in many instances there are important thresholds

which determine the severity of response. Climate change impact is undoubtedly the most important focus of coral reef research in all disciplines at present. To some extent, the situation is similar to that of the nineteenth century when conflicting hypotheses on the formation of coral reefs were the highlight. Then, as further research revealed the depth and lithology of the foundations, ideas on glacially controlled sea levels became accepted and the whole new scenario of plate tectonics was revealed, it became clear that as in many areas of science, there may be more than one correct answer to a problem. As more thresholds are determined, different options for coral reefs to move into the future will become apparent. Unfortunately, these will mostly be under adverse conditions.

Climate change and coral reefs form one of the major foci of this encyclopedia. Although entries are presented in alphabetical order, they have been organized under major compilation headings which should become particularly obvious when the reader uses the cross-references with each entry. Theories and hypotheses, from Darwin to climate change, also provide a substantial number of entries, together with some of the major methodologies used in the hypothesis testing. Short biographies are given of some of the major contributors to the study of coral reefs in the earth science field, including organizations. Classifications of various features are given, which again show that there may be more than one critical approach to features or processes. Although the encyclopedia does not contain a formal glossary, there are many short entries explaining specific features or processes. As coral reefs vary around the world, a significant number of entries have been devoted to geographical areas. Finally, the past contribution to modern reefs is not forgotten with contributions on specific reef complexes of the geological past, whilst the future, however fragile, is assessed through a number of contributions on conservation.

This is not an exhaustive list but hopefully, it gives a structure to the encyclopedia's contents. Of equal value are the many references given with the entries. These range from some of the most classical to material only published in the last 12 months. The interest in coral reefs is such that, over the next few years, further interesting material will be published and updates may be required, but the 260 entries within the present volume, written by authors from 15 different countries, give a wide perspective of earth science's interest in an increasingly fragile ecosystem.

David Hopley  
September 2010

## Acknowledgments

A work the size of this encyclopedia inevitably relied on the help and cooperation of a very large number of people, only some of whom can be identified. My particular thanks go to the Editorial Board, an international group of highly respected coral reef scientists. To Guy Cabioch, Peter Davies, Terry Done, Eberhardt Gischler, Ian Macintyre, Rachel Wood, and Colin Woodroffe, thank you for keeping this project on course by helping to choose the topics which form the entries, suggesting high-quality authors, reviewing the initial manuscripts, and finally checking the proofs with your selected groups of authors as well as writing important contributions yourselves.

This leads to the largest group I wish to acknowledge, the authors of the 260 entries which range in size from a few hundred words up to major contributions of 10,000 words. Many authors have also taken on more than one entry within their speciality area. Also, with authors from 15 different countries for many, English is not their first language, yet, with help from the Editorial Board and from Springer, they have provided quality articles. Inevitably, with such a large group of people there have been problems with illness, with members of their family, etc. and yet, the overall production has not deviated to any great extent from the original timetable. The writers of the articles are highly commended for their dedication to the work.

At the production end of this project has been the staff of Springer. Their help, understanding, and cooperation, especially when small problems arose, is something I cannot appreciate enough. Their patient collaboration with authors and board did much to maintain the smooth timetable. Special acknowledgment must go to Petra van Steenbergen, Sylvia Blago, and Simone Giesler, who were involved with the encyclopedia from start to finish, a period of over 3 years. In particular, their decision to accept so many color illustrations has done much to add to the attractiveness and interpretation of these entries on coral reefs. Advice, especially in the formative stages, from Charlie Finkl, himself a coastal scientist, and a Series Editor for the *Encyclopedia of Earth Sciences Series*, did much to guide the project along the most effective tracks.

In many works like this, thanks are expressed to the editor's/author's spouse for their patience and support. My appreciation to Patricia goes far beyond this as without her many hours of support, the project would not have been completed. Not only did she run an efficient office, maintaining a most complex filing system and, due to my own deficiencies, taking on responsibilities for all communications but also she provided continuous motivation through the many hours she spent, furthering the project.

Finally, to the many unnamed people who have contributed to the encyclopedia, thank you for your time and effort and I hope the final product meets with your approval.

## ACANTHASTER PLANCI

---

Ian Miller  
Australian Institute of Marine Science, Townsville,  
QLD, Australia

*Acanthaster planci* (Class Asteroidea; Order Spinulosida; “crown-of-thorns sea star or starfish”) is a large (up to 70 cm), mobile, multi-armed (7–23) sea star covered in sharp, toxic spines. It feeds almost exclusively on hard corals and is found on coral reefs throughout the Indo-Pacific. No other reef sea stars remotely resemble its appearance, nor possess comparable life-history traits as a predator on corals.

Crown-of-thorns are prone to population outbreaks, with aggregations of thousands or more adults per hectare not uncommon (Figure 1). Such populations often advance in fronts through coral habitat, leaving formerly luxuriant coral areas dead in their wake. The sea star has a number of life history traits that predisposes these destructive population outbreaks: absence of any equivalent coral predator (little competition for food); a large stomach (that is pushed out through the mouth to digest coral tissue externally); a high fecundity (a mature female can produce some 50 million eggs); planktonic larvae (that can feed in the water column and disperse over long distances); rapid growth ( $\sim 10 \text{ cm.y}^{-1}$ , that is faster than any other coral reef sea star); large size and toxic spiny armature (that provide protection from potential predators); multi-armed morphology and tube feet (allowing them to climb and feed in nearly any position). Repeated population outbreaks have decimated hard corals throughout the Indo-Pacific over the last 50 years.

Outbreaks were first observed in the 1960s. The geographical extent (two oceans) and impact (an ecosystem changed from one dominated by hard corals to one dominated by algae), shocked scientists. A key management issue was whether human activity had somehow precipitated the population outbreaks. Two main hypotheses have been developed that implicate anthropogenic factors. The first is “the predator removal hypothesis” (Endean, 1969), which holds that overfishing (in particular sweetlips (Family Lethrinidae), some wrasses (Family Labridae) and some triggerfish (Family Balistidae)) and collecting of predators of the sea star (notably a large Gastropod mollusc the giant triton *Charonia tritonis*), allow crown-of-thorns to build up in numbers on a reef. On reaching a critical abundance, their reproduction and larval dispersal leads to successful recruitment of larvae on reefs downstream in prevailing currents. A cascade of outbreaks across tracts of neighboring reefs ensues. The second hypothesis (possibly synergistic with the first) is “the nutrient enrichment hypothesis” (Birkeland, 1982, Lucas, 1982). In this scenario, river runoff from human-modified catchments enhances nutrients in coastal waters, resulting in an increase in phytoplankton upon which the sea star larvae feed. Because crown-of-thorns produce such a vast quantity of eggs even a small increase in survivorship leads to larger settlement of larvae onto a reef, which in turn leads to a primary outbreak.

Today, despite repeated outbreaks and years of research the exact events leading to the initiation of an outbreak remain enigmatic. This is because the life-history of crown-of-thorns makes it difficult to disentangle the natural processes leading to an outbreak from those forced by human activities. As a result crown-of-thorns remains a major management problem for coral

**Acanthaster Planci, Figure 1** A crown-of-thorns feeding aggregation. Such outbreaks of the sea star are a major recurrent cause of coral mortality on coral reefs throughout the Indo-Pacific (photo: AIMS LTMP).

reefs. Where adults have been collected as a control measure, coral has been saved from predation only over relatively small areas (hectares). In the past, coral cover has generally recovered within 10–15 years of an outbreak. However coral resilience in the face of future outbreaks is uncertain (Done, 1987). This is because the size and frequency of other impacts that can effect coral reefs (such as cyclones, coral bleaching, and ocean acidification) are predicted to increase in coming years due to greenhouse gas emissions. Without full recovery, repeated outbreaks will eventually lead to the degradation of the coral reef community.

## ACCOMMODATION SPACE

Tom Spencer  
 University of Cambridge, Cambridge, UK

### Definition

The space available, in both a vertical and a lateral sense, within which corals can grow, increase framework and sediments accumulate.

### Accommodation space

For corals, accommodation space is constrained vertically by the water-air interface and its volume broadly determined by reef widths and slope angles. For sedimentary accumulations on reef platforms, the lower boundary is governed by reef margin position, reef flat elevation and lagoon depth and the upper boundary set by the height of wave run-up during storm events. The rate at which accommodation space can be filled depends upon rates of vertical coral growth, vertical framework accretion and sediment supply, transport and accumulation; these are all controlled by reef productivity and sediment generation processes which may themselves be constrained by the environment processes (e.g., wave exposure locally prevents coral growth from filling accommodation spaces on Hawaii; Grigg, 1998), be periodically interrupted by storms (see *Tropical Cyclone/Hurricane*) and modulated by sea level change, which ultimately determines the upper margin of the accommodation space (Figure 1).

Over the long-term, a subsiding reef basement results in an increase in accommodation space. During glacial periods, emergent reefs were subject to subaerial solution, thus increasing the vertical accommodation space available for reef re-growth on renewed inundation during interglacial periods. There has been debate over the subaerial erosion rates involved, and thus the additional accommodation space generated, ranging from minimal downwearing (e.g., Quinn and Matthews, 1990) to 6–63 cm of surface lowering per 1,000 years (e.g., Gray et al., 1992). During the stable sea-level of the late Holocene, there has been “turn-off” of both vertical and horizontal growth of some reefs due to the progressive thinning of accommodation space as reefs approached present sea level (which itself may have fallen slightly in some Indo-Pacific locations, thus further reducing accommodation space) and the difficulty of lateral expansion, and maintenance of reef front volume and integrity, over relatively unstable reef front talus deposits in increasing water depths. For example, Smithers et al. (2006) attributed the shut-down of fringing and nearshore reef progradation on the Great Barrier Reef between 5.5–4.8 ka BP and 3.0–2.5 ka BP to the contraction of accommodation space caused by the reefs’ own growth and the complete occupation of favorable reef foundations. In the short term, local accommodation space is an outcome of local reef erosion and the re-configuration of sedimentary accumulations resulting from hurricane and

**Accommodation Space, Figure 1** Different models of fringing reef development show different modes of accommodation space filling. (a): accommodation space is filled by corals showing catch-up or keep-up behavior. (b): reef accretion is lateral, having established at a level with little or no vertical accommodation space. Isochrons are in thousands of radiocarbon years BP (From Kennedy and Woodroffe, 2002).

cyclone impacts (see *Tropical Cyclone/Hurricane*). It has been argued that rates of sea level rise of  $\sim 0.5$  m by AD 2100 might create new accommodation space and switch reef vertical accretion back on, with carbonate production for the entire Great Barrier Reef rising from the current estimated  $50 \text{ Mt a}^{-1}$  to  $70 \text{ Mt a}^{-1}$  (Kinsey and Hopley, 1991).

### ACROPORA

Carden C. Wallace  
Museum of Tropical Queensland, Townsville, QLD,  
Australia

### Synonyms

Arborescent corals; Axial branching corals; Midori ishi (Japan); Staghorn corals; Table corals

### Definition

*Acropora* (Oken, 1815) is the type genus of the hard coral family Acroporidae (class Anthozoa, order Scleractinia

of the phylum Cnidaria). Currently, around 120–140 living species are recognized in this genus, but new species are still being discovered in both living and fossil coral assemblages. The Latin name derives from the growth mode, where branches are formed by a central or axial polyp, which buds off numbers of a second kind, the radial polyps, from around its tip as it extends. New branches are formed by the development of new axial polyps along the branch. This mode of growth, which is similar to the axial mode in flowing plants, allows many variations on a branching theme (Figure 1). It is thought to have been a key character in the evolution of a diverse array of species in *Acropora*, although other processes are also proposed, such as hybridization and reticulate evolution facilitated by the mass spawning of related species.

### Introduction

Six coral families (Acroporidae, Faviidae, Mussidae, Poritidae, Fungiidae, and Pocilloporidae) dominate modern world reef composition, in terms of diversity, abundance, geographic range, and contribution to accretion of reef carbonates. Of these, Acroporidae is arguably the most successful, as the two most species-rich genera, *Acropora* and *Montipora*, allow it to dominate the species diversity and coral cover of most Indo-Pacific reef locations. *Acropora* the “staghorn” corals have played a role in the biodiversity, ecology, and structure of coral reefs for almost 60 million years (Schuster, 2003; Wallace and Rosen, 2006). Their mode of skeletal construction, where polyps are supported within an open “synapticular” framework (Figure 2), allow for rapid growth with efficient use of calcium carbonate (Gladfelter, 2008) and provide habitat complexity for other reef biota (Munday, 2002). Strong representation in mass coral spawning and recruitment events, and rapid recolonization after destructive natural events are the characteristics of *Acropora* (e.g., Babcock et al., 1986; Connell et al., 2004): however, this genus may experience severe localized or widespread loss of diversity from major perturbations such as coral bleaching due to elevated seawater temperature, cold-water events, tsunamis, cyclone damage, and predator population outbreaks, particularly of *Acanthaster planci*, the crown-of-thorns sea star (Wilkinson, 1998–2008; Berklemans et al., 2004; Marshall and Baird, 2006). Chronic anthropogenic impacts such as nutrient and sediment run-off,

**Acropora, Figure 1** Examples of colony shapes in *Acropora*: (a) Arborescent (*A. grandis*), (b) Arborescent table (*A. valenciennesi*), (c) Corymbose (*A. anthocercis*), (d) Digitate (*A. gemmifera*), (e) Hispidose (*A. echinata*), and (f) Table (*A. clathrata*). (Photos: P. Muir.)

overfishing, and coral mining for limestone also have an impact on *Acropora* (Fabricius, 2005; Fabricius and Wolanski, 2000; Brown, 1997).

### Nomenclatural issues

Until the late nineteenth century *Acropora* was known mostly as *Madrepora*, a broadly applied name, which is

now restricted to a genus of non-zooxanthellate deepwater corals. The name *Acropora* was stabilized by a decision of the International Code of Nomenclature in the mid-twentieth century (Boschma, 1961; China, 1983), which also ruled on a type species, *A. muricata* (Linnaeus, 1758). A dilemma concerning the nature and provenance of this species, described by Linnaeus as being from the

**Acropora, Figure 2** (a) Synapticular formation of *Acropora* skeleton, shown in scanning electron micrograph of *A. abrotanoides*. Also seen is the axial corallite (a) and radial corallites (r) (Scale: 500  $\mu$ m). (b) High power SEM of synapticular formation in *Acropora nasuta*. Two synapticalae approaching each other will form a node (n), from which another synapticala will develop at right angles (Scale: 100  $\mu$ m). (Photos: P. Muir and C. Wallace.)

“Asian Sea,” was resolved by designation of a neotype from central Indonesia (Wallace, 1999). The size of the genus was reduced slightly by elevation of a subgenus *Isopora* to separate genus status because it differed from other *Acropora* in skeletal and reproductive morphology as well as reproductive mode (Wallace et al., 2007). The remaining species are organized into 20 species groups based on skeletal features (Veron and Wallace, 1984; Wallace, 1999). Genetic studies are revealing numerous dilemmas about species boundaries (Van Oppen et al., 2001, 2002) and at least one named species of *Acropora* is now known to be an F1 hybrid (Van Oppen et al., 2000; Vollmer and Palumbi, 2002).

### The skeleton and polyps

All scleractinian corals have skeletons of the crystal aragonite form of calcium carbonate, but formation of a skeleton by the polyps follows different patterns among families, giving structural features by which corals can be identified in both living and fossil form (Wells, 1956; Roniewicz, 1996). In Acroporidae, most components of the skeleton are formed by the development of simple rods or “synapticalae,” which allow for a strong but light and open growth (Figure 2; Nothdurft and Webb, 2007; Rosen, 1986). The potential of this mode for rapid growth in three dimensions is exemplified by the axial growth of *Acropora*. This provides a light scaffolding to support the living colony and allows organization of the tissues into a gastrovascular system in which flagellated gastrodermal cells promote laminar flow up, down and around the branch to transport water and nutrients. The axial polyp extends through most of the branch and is thus much longer than the radials. A notable aspect of the growth mode of *Acropora* is that some species have symmetrical growth around a central growing point and maintain a limited “determinate” pattern of growth, while others exhibit unlimited and asymmetrical growth, filling

in available space wherever it comes up. These contrasting modes allow *Acropora* colonies to efficiently fill available space on the reef (see Figure 3a). The polyp cavities are extended by the coenenchyme, a complex network of tubules containing extensions of the gastric cavity. Much of the skeletal variation used for taxonomic delineation of species comes from the shape of the radial corallites and the microstructure of the skeleton (Wallace, 1999). Another form of skeleton, the epitheca, formed by calcite form of calcium carbonate, is present in very small quantities below the living tissues of the branch and acts as a sealant preventing infection and protecting the live polyps and coenenchyme from fluid loss (Barnes, 1972). The polyps of *Acropora* have a simple tubular structure and 12 tentacles, one of which extends greatly as a “catch tentacle,” particularly when the polyps are feeding at night (Wallace, 1999). Below the tentacles are the mesenteries, which carry the gonads when they develop and have a muscular internal filament, which can extend outside the polyp for defense, clearing space, and possibly feeding (Roff et al., 2009).

### Habitats and ecology

*Acropora* is often interpreted as being a reef-front genus, favoring sites with good circulation, high oxygen content due to the strong movement of water, and access to food from oceanic waters. While a diverse “*Acropora* zone” from the reef top to about 12 m depth, is indeed a characteristic of most oceanic Indo-Pacific reefs, this genus also occurs significantly in specialized habitats such as sandy lagoon floors, deep reef slopes and deepwater *Halimeda* banks, and in relatively turbid fringing reef locations. The persistence of an abundance of colonies and diversity of species through time on any reef habitat relies on a complex interaction of water quality and physical and biological parameters: the activities of other reef organisms also impact on survivorship at each life stage

**Acropora, Figure 3** (a) Numerous forms of *Acropora* maximize usage of three-dimensional space in shallow reef shoals: ten species occupy this frame. (b) Steep walls support mainly small plates which maximize exposure of the polyps to light. (Photos: P. Muir.)

and compete with corals for resources (Done, 1999; Done et al., 2007). Human-influenced deterioration of conditions suitable for survival and/or settlement of *Acropora*, or favoring survival and population increase of other benthic organisms such as the coral genus *Porites*, soft corals, and algae, are thought to be involved in the gradual deterioration of *Acropora* communities in many parts of the world and to threaten the survival of the rarer or more narrowly distributed species of this genus (McClanahan et al., 2008). Many rare species may be threatened by diminishing habitats (Carpenter et al. 2008), although it has been suggested that some rare species with small global population sizes are actually unidirectional hybrids, and that this contributes to increased genetic variability and adaptive potential, making them less vulnerable to extinction (Richards et al., 2008). In the Caribbean, the two major *Acropora* species *A. cervicornis* and *A. palmata* have undergone massive population loss over recent decades in many locations as a result of exposure to repetitive hurricanes, coral diseases, changes in water quality, and outbreaks of other reef organisms (Bythell et al., 1993; Williams et al., 1999) and such rapid declines appear to be unprecedented in the past 4,000 years (Aronson and Precht, 1997).

### Sexual and asexual reproduction

Species of *Acropora* reproduce sexually by developing gametes (eggs and sperm) along the mesenteries (radial dividing structures) within the polyps. In *Acropora* polyps have both sexes (hermaphrodite), with certain mesenteries bearing eggs and others sperm (Wallace, 1985) (Figure 4). Fertilization takes place externally, after the gametes are released into the water column, often during mass spawning events involving many species. The fertilized eggs develop into ciliated larvae known as planulae,

**Acropora, Figure 4** Egg sperm bundles of *Acropora tenuis* leaving polyps and ascending into the water column, during a mass spawning event on the Great Barrier Reef, Australia. (Photo: Z. Florian.)

which spend some days in the water before being ready to settle on reef surface to begin a new colony. Planulae remain viable for days to weeks and may be transported long distances and settle away from the home reef. This contrasts with sexual reproduction in the sister genus *Isopora*, where sperm is released but the eggs stay within the polyp, where they are fertilized by sperm from other colonies and develop into larvae which are released ready to settle on the reef. The two contrasting modes of reproduction may have different consequences for the genera after loss of the adult corals in a population: for *Acropora*, the possibility of recruitment of larvae from healthy reefs is greater. This has been seen after mass bleaching of *Acropora*, for example, in the Maldives (Wallace and Zahir, 2007) and Socotra (western Yemen), where

*Acropora* recruits were visible several years before the appearance of *Isopora*, following the 1998 bleaching event (L. DeVantier, personal communications).

### Genetics and phylogeny

*Acropora* has a large and complex genome and this has been studied in detail for certain species and species groups as well as in the context of genus-level phylogenies. Molecular (genetic) studies show corals to have two main evolutionary lines, known currently as the “Robust” and “Complex” clades. *Acropora* and other members of the family Acroporidae fall within the Complex clade (Romano and Cairns, 2000; le Goff-Vitry et al., 2004; Chen et al., 2002). Evolution of the mitochondrial genome of all Anthozoa is typically slower than that of other animals, making it difficult, for example, to use cytochrome b to study population genetics in these animals, but it is faster in *Acropora* than in confamilial genera (Van Oppen et al., 1999). The tempo of evolutionary change is faster in the nuclear and slower in the mitochondrial genomes for *Acropora* (and other corals studied), making them more similar to plants than other animal groups in this respect (Hellberg, 2006; Chen et al., 2009). Genetic studies and laboratory cross-fertilization experiments on *Acropora* from within species groups (especially the *A. aspera*, *A. cervicornis*, and *A. humilis* groups) have indicated that hybridization and introgression may play a significant role in maintaining variety within populations and associations of *Acropora* species, perhaps contributing to resilience in the face of adverse conditions (Van Oppen et al., 2000; Wolstenholme et al., 2003). These and many other genetic findings for *Acropora* and other corals are contributing to a major revision of the characteristics and relationships within the order Scleractinia. Because corals have a hard skeleton and this remains after death, there is a superb fossil record and long-known paleontological information is currently being integrated with the molecular results to develop a new overview of relationships and evolution.

### Biogeography and evolution

The greatest living diversity of *Acropora* is seen in Indonesia, where 91 species have been recorded (Wallace, 2001) and similar numbers are present in the Philippines and Papua New Guinea. The Indonesian diversity is greatest within the region known as “Wallacea,” that is, the region of islands between the Asian and Australian continental shelves (Wallace, 2001). The Indonesian *Acropora* diversity includes species with very extensive Indo-Pacific ranges, others restricted to the central Indo-Pacific, and yet others which have either predominantly Pacific Ocean or Indian Ocean distribution, with some overlaps in Indonesia. (Wallace, 2001; Wallace et al., 2001). In the Caribbean, only three living species occur. Through post-Cretaceous time, *Acropora* has been present in all the major reef-bearing parts of the world, including

the fossil deposits of the Middle East and Europe, fossil and modern reefs of the Caribbean and the Indo-Pacific, where the majority of the living species occur. It is known in the fossil record from the Paleocene of Somalia (approx. 60 million years ago) and was possibly present before the end of the Cretaceous (Baron-Szarbo, 2006). Nine of the twenty species groups are represented in the mid-Eocene fossil record of England and France and this is taken to indicate that the diversification of this genus began well ahead of its later Indo-Pacific diversification (Wallace, 2008). Several species of *Acropora* also await description from the Oligocene to early Miocene of Europe and Miocene-Pliocene of the Caribbean. The first case of *Acropora* being abundant and dominant on a coral reef is seen in the Oligocene of Greece (Schuster, 2003).

### Summary

*Acropora*, the staghorn coral genus, has persisted for some 60 million years and now remains in living form in the Caribbean and the Indo-Pacific, the two main reef-bearing regions of the world. It is regarded as extremely successful because it contains the greatest number of species of any coral genus, and its species typically occur in great abundance. While it plays a major role in many aspects of reef ecology, *Acropora* has been shown to be extremely vulnerable to major disturbances on reefs, and thus there is concern about its persistence into the future, in the face of changes due to bleaching, disease, and other factors resulting from global climate change. The fossil record tells us that this genus has persisted and diversified through time, and genetic research is indicating that rare species may have a resilience to local extinction because of the potential for hybridization with other species. Recent decadal changes in both the Caribbean and the Pacific, however, show that *Acropora* can undergo local extinction in certain circumstances. It is clear that the future of this coral genus is intimately linked with the future of the world’s coral reefs.

## ADAPTATION

David Obura  
 CORDIO East Africa, Mombasa, Kenya

### Definition

*Adaptation* is the process of change in the structure or function of an organism or parts of an organism that makes it better suited to the environment in which it lives. Adaptations (or traits that are adaptive) that are heritable, i.e., coded in genes or that have consequences on the reproductive success of genes, contribute to natural selection.

*Acclimatization* refers to adjustment to local conditions that occurs within the lifetime of an individual, in response to external environmental conditions, for example, through behavioral changes, or increased tolerance of stressful conditions. *Acclimation* is similar, though is applied more narrowly to artificial conditions and experimentation. Both can lead to true adaptation if and when the relevant traits are passed on to the next generations.

### Introduction

Adaptation is a core concept of evolutionary biology, its significance recognized by Charles Darwin (*Darwin, Charles (1809–1882)*) as a central tenet of his theory of evolution by natural selection (Darwin, 1856). Simply stated, differences in individuals of a species, or among species, may confer differential survival or performance, and thus influence which individuals survive and

reproduce, and thereby the passing of favorable traits on to offspring. Where traits shift or adjust to suit local conditions, beneficial ones can be viewed as “adaptations,” and may confer evolutionary success.

Adaptation is a whole-organism phenomenon. Change in a trait that confers benefits in one area but imposes costs or dysfunction in another may not lead to adaptation if the costs outweigh the benefits. Thus tradeoffs between traits are an essential part of the process of adaptation, placing constraints on what changes are beneficial. This is recognized in life history theory, which relates how organisms divide limited energy and resources to different functions and processes, how the balance between these may change with external conditions, and how these changes result in differential success among life history strategies (Stearns, 1992).

Adaptation is such a wide-ranging process that generalizations about it are often not true in all conditions. For example, severe environmental conditions may pose strong selective pressures leading to rapid adaptation to environmental stress in that part of the population that survives (Hoffman and Parsons, 1991). In this case, adaptation occurs by extermination of “unfit” genes under rapid environmental change. On the other hand, benign conditions enable beneficial traits to accumulate in a population over successive generations. In this case, adaptation occurs by competitive success of beneficial genes over less-fit genes. Not all traits that occur in an organism are certain to be adaptive; they may simply not have a negative impact on the individual’s or species’ survival. Thus, it is necessary to determine specifically if a trait is adaptive through careful observation or experimentation, rather than by simply observing its presence (Gould and Lewontin, 1994). The evolution and taxonomy (*Coral Cay Classification and Evolution*) of extant reef corals provides key insights into the unusual evolutionary pressures faced by corals and hence of their capacity for adaptation.

Coral reefs are typically considered to occur in relatively benign and stable environmental conditions (*Corals: Environmental Controls on Growth*), with high density and diversity of organisms. This creates conditions for high levels of niche diversification and diversification of interactions, and for these to become stable over time. Thus adaptation, or coadaptation (among mutually interacting species), is common on reefs and can be distinguished in many forms of interactions, such as:

1. Primary production: Different functional groups of primary producers, characterized by whether they form hard crusts that resist herbivory and cement reefs, fast-growing low-biomass algal filaments and turfs with high recovery rates from removal, and large-bodied fleshy algal fronds that resist herbivory through low palatability and compete with other sessile organisms to monopolize space (*Algae, Coralline; Algae-Macro; Algae, Turf*);
2. Predator–prey dynamics: A vast array of different prey and predators, and of defense and predation mechanisms. Adaptations of fish consumers are clear in their jaw structures toward their prey (*Figure 1*): scraping

herbivores with hard fused teeth that can graze algal crusts, fish with long tubular mouths for sucking polyp tissue out of a coral skeleton, or top predators with needle-sharp pointed teeth for grabbing fast swimming prey and holding it until it can be torn and swallowed. Defense mechanisms may be even more numerous including chemical defenses of unpalatable algae and invertebrates that produce toxins, hard-shelled defenses such as in snails and crustaceans, or mimicry by palatable species of unpalatable or poisonous species often in completely different taxonomic groups;

3. Mutualisms: With limited space on a coral reef, numerous organisms adapt to live together cooperatively, in stark contrast to predator–prey or competitive interactions, in which one wins over the other. Many species live in or on one another, such as many types of crustaceans and anemones living on anemones and hard and soft corals, or fish and shrimp that share skills to build, maintain, and defend a burrow, or of microscopic single-celled algae such as zooxanthellae living in the tissue of a host such as a coral, to the mutual benefit of both.

### Coral–zooxanthellae symbiosis as an illustration of adaptation

The symbiosis between corals (the host, a sessile macroinvertebrate) and its zooxanthellae (the endosymbiont, an autotrophic single-celled algae) is the example *par excellence* of a type of partnership that has recurred among different partners in shallow tropical seas for hundreds of millions of years. The host is attached (sessile) on a shallow bottom, providing a sheltered nutrient-rich microhabitat in the photic zone for the endosymbiont. The endosymbiont fixes energy of sunlight into carbohydrates, which are passed to the host for consumption, and may also enhance the intracellular chemical environment for cellular processes of the host, such as calcification (*Corals: Biology, Skeletal Deposition, and Reef-Building*). The adaptations enabled by this symbiosis can be illustrated at physiological, organismal, and ecological–geological scales.

Because the symbiosis combines two organisms – a photosynthetic algae and a consumer animal – two forms of energy capture and nutrition are possible. Under low-nutrient, high light conditions, photosynthesis is maximized, tight nutrient-cycling between the symbiotic partners enables growth in both, and autotrophy is the dominant mode of energy capture for the holobiont. By contrast, in highly turbid environments with limited light, heterotrophy by the coral predominates. Under these conditions feeding by the coral on plankton, detritus, and dissolved organic matter (*Corals: Environmental Controls on Growth*) may compensate for limited autotrophy and enable corals to thrive. The reliance of different coral species on autotrophy vs. heterotrophy, and their ability to shift

**Adaptation, Figure 1** *Top* – butterflyfish (Chaetodontidae) have long tubular mouths for sucking polyp tissue out of a coral skeleton, and a flattened shape for maneuvering in narrow spaces between coral branches. *Middle* – hawfish (Cirrhitidae) live on and within coral colonies. *Bottom* – parrotfish (Scaridae) have hard fused teeth that can graze algal crusts and excavate the rock substrate.

**Adaptation, Figure 2** Growth form adaptations of *Pocillopora damicornis*, which forms thin delicate branches in calm and deeper conditions (top) and thick robust branches in shallow rough conditions (bottom).

between the two, differs, reflecting adaptations to different environments and ecological niches.

At the organismal level, a classic example of the adaptability of corals is in the diverse growth forms possible in some species. For example, growth form may vary depending on hydrodynamics (affecting how robust the skeleton must be) or light and sediment regimes (affecting shape, orientation, and self-shading (*Corals: Environmental Controls on Growth*). *Pocillopora damicornis* is a fast-growing, opportunistic, branching coral species that illustrates this well (Figure 2): individuals growing in calm and light-limited conditions may have very fine branches (no selection for robust growth but strong selection to minimize self-shading) while individuals of the same species in rough, well-illuminated environments may have very robust branches (resistant to breakage, no need to minimize shading effects). Individual colonies from the extremes of these distributions may appear so different that

without intermediate growth forms being known, these may appear to be separate species (Veron, 2000). Further adaptations of growth form can relate to, for example, sediment shedding in high-sediment conditions.

The ability of coral holobionts to calcify extremely efficiently and thereby produce durable skeletons has enabled successive generations to colonize the skeletons left by previous generations and thereby raise up above the substrate resulting in reef construction over time (*Coral Reef, Definition*). The specific growth forms and other adaptations of the dominant corals in these communities affect the morphology and development of *Reef Structure*. Over geological history different but functionally equivalent symbioses have recurred: rugose corals in the Palaeozoic; rudist bivalves in the Cretaceous; scleractinian corals in the Cenozoic. The fossil reefs they have left behind show characteristic adaptations to the periods in which they lived.

### Current investigations, controversies, and gaps in current knowledge

#### Coral bleaching

The life history of symbiotic corals and the as-yet incompletely understood phenomenon of coral bleaching (*Temperature Change: Bleaching*) provide an interesting case study of adaptation in action. As currently understood, the coral host provides a safe habitat and nutrients to the endosymbiotic algae. They in turn contribute to a range of the coral host's physiological processes by transferring energy from sunlight in the form of fixed carbon, and chemically facilitating a variety of intracellular processes, such as calcification (Muscatine, 1990). The symbiosis is obligate because coral species that are symbiotic do not successfully compete in nature when asymbiotic. However, the symbiosis can be disrupted temporarily as happens under stress (e.g., heat, cold, hyposalinity) when the symbionts part company and the coral “bleaches,” or turns white (Figure 3). This occurs by a reduction in the photosynthetic capacity of the holobiont (by reduction in chlorophyll concentration in individual symbionts, and/or by reduction in symbiont densities), primarily to counter the damaging effects of overproduction of free oxygen radicals by the symbionts.

As a stress response, bleaching must have some capacity for acclimatization and adaptation (Coles and Brown, 2003; Obura, 2009). The Adaptive Bleaching Hypothesis first expressed this idea as a mechanism that allows coral symbionts to adapt to changing environmental conditions (Buddemeier and Fautin, 1993), a position countered by other on the grounds of insufficient evidence (Hoegh-Guldberg, 2005). Further advances in the field may come through seeing bleaching as an extreme state of a range of symbiotic responses to changing environmental conditions (Obura, 2009). These include, from least to most severe: fluctuating symbiont densities, such as occur under

**Adaptation, Figure 3** Bleaching of corals has been portrayed as an adaptation for the coral–zooxanthellae symbiosis to resist stressful conditions, whereby zooxanthellae and/or chlorophyll is lost such that the normal color of the coral (*left panel*) fades such that the white skeleton becomes visible through the transparent coral tissue (*right panel*). All hard coral genera may bleach; shown here are the genera *Pocillopora* (*top*), *Galaxea* (*middle*), and *Lobophyllia* (*bottom*).

normal seasonal changes in the environment; shuffling between different clades of symbionts already in the coral, in response to more extreme environmental fluctuations; taking on new symbiont clades from the water column, after bleaching caused by severe stress. In the latter case,

the switch to different symbionts may be a temporary response to severe stress, with reversion to normal symbiont populations following a return to normal conditions.

There are tradeoffs between high growth and reproduction versus slow growth and stress resistance that affect the bleaching response of corals, illustrating the adaptive dimensions of bleaching. Corals characterized by rapid growth and reproduction and thin coral tissues tend to bleach and die at lower levels of stress (e.g., *Acropora*, *Pocillopora*), while those characterized by slow growth and thick coral tissues tend to bleach and survive at higher levels of environmental stress (e.g., *Porites*) (Loya et al., 2001). Greater tissue thickness and larger polyp size may be adaptive through their shading of zooxanthellae, ameliorating stress from high light and temperatures.

### Long-term change

Global climate change (*Climate Change and Coral Reefs*) is proceeding in multiple environmental parameters critical to coral growth and survival. Water temperature and acidification of ocean waters are two of the fundamental ones (Hoegh-Guldberg et al., 2008), in addition to many others such as changes in sea level, storm tracks, wave regimes, precipitation, and terrestrial runoff that will affect reef growth. The ability of corals and zooxanthellae to adapt to the changes in these basic environmental parameters will fundamentally affect their ability to continue to grow and build reef structures.

Increases in the frequency and severity of coral bleaching events globally are an indicator of water temperatures exceeding the temperature envelopes to which corals are historically adapted. The adaptive potential of bleaching and other regulatory processes is currently unknown (Hughes et al., 2003), however the adaptive basis for coral bleaching explained above, and scenarios for the degree of adaptation needed for corals to survive future change (Donner, 2009), provide tools for understanding this process as it unfolds. The adaptive potential of corals to seawater acidification is less known than that for temperature, and as a basic chemical parameter controlling calcification it may be that there is very little ability for corals and other calcifying marine organisms to adapt to more acidic conditions (*Ocean Acidification, Effects on Calcification*). In this time of global change, the adaptive capacity of corals will be a critical feature in determining how reef ecosystems respond to change.

## AERIAL PHOTOGRAPHY OF CORAL REEFS

David Hopley  
 James Cook University, Townsville, Queensland,  
 Australia

### Aerial photography of coral reefs

Because of the complexity of coral reefs and difficulties in ground survey, the reef environment was one of the

earliest to take advantage of remote sensing techniques (Hopley, 1978). Both aircraft and balloons (e.g., Rützler, 1978) formed the initial platforms, usually for vertically mounted cameras using black and white film. On the Great Barrier Reef (GBR), the earliest vertical aerial photography was in 1925, when the Royal Australian Air Force photographed the Low Isles at a scale of 1:2,400 in 1928 for the Yonge Expedition (see [Great Barrier Reef Committee](#)). Simultaneously, Umbgrove (1928, 1929) was photographing reefs in Indonesia to aid the extensive work he was carrying out there.

Aerial photography was used in many reef studies for the next 50 years, though systematic approaches were rare (Steers, 1945; Teichert and Fairbridge, 1948, 1950). Color photography was used in some areas, especially those related to tourism projects. Between 1964 and 1972, the whole of the GBR was photographed at scales between 1:50,000 and 1:80,000 (later to be used in combination with satellite imagery in providing the detail for the first zoning maps of the GBR Marine Park, Hopley et al., 1989). In the 1970s, experiments were made with emulsions outside the visible range. For example, it was found that the near infrared part of the spectrum (0.7–0.86  $\mu\text{m}$ ), though giving poor water penetration, uses its whole tonal range over only a meter or so of water depth, i.e., was ideal for mapping exposed reef flats at low tide. Moreover, the zooxanthellae within the coral tissue, like terrestrial vegetation, provides a very strong reflective signal (Hopley and van Steveninck, 1977) (Figure 1). Initial experiments were made using both color and near infrared film from flying heights as low as 1,000 ft (Linfoot and Thamrongnawasawat, 1993; Thamrongnawasawat and Catt, 1994; Thamrongnawasawat and Hopley, 1995), providing pixels of <25 cm (Figure 2). As detailed in the quoted references above, the optimal flying height for the Hasselblad Single Lens Reflex 500 EL/M camera used was found to be about 3,000 ft (914 m). A digital image processing system called BRIAN or microBRIAN (Jupp et al., 1985) was used to analyze the scanned data.

**Aerial Photography of Coral Reefs, Figure 1** Branch of living *Acropora* sp. just removed from water and displaying strong near infrared reflectance from the symbiotic zooxanthellae.

**Aerial Photography of Coral Reefs, Figure 2** Color near the infrared photograph from ~5,000' (1,524 m) of Wheeler Reef near Townsville on the Great Barrier Reef. Tide was a Spring low and features on the reef margin with healthy coral cover show a stronger reflectance than those on the main reef flat, where ca. 0.25 m water cover reduces the IR penetration.

Image combination techniques were applied to merge each pair of true color and infrared digitized photographs into one imagery file (Kuchler, 1984).

While, the near infrared image can penetrate only 1 m of water, the detail of reef flat morphology noted above is very apparent (Figure 3) and it complements the 15–20-m-depth penetration of the color image. Advantages are high resolution, choice of timing (though weather dependent), and modest cost. In an initial experiment mapping Marine Park coral reefs in Thailand for management purposes, it was possible to differentiate between reef flat head and branching corals, seagrass beds and nonliving substrate, with an accuracy between 86.7% and 100% (Thamrongnawasawat and Hopley, 1995). Mumby and Green (2000) provide a critique of the digitized aerial photographic methodology, concluding that it is ideally suited to small area survey.

However, as the resolution and spectral cover of satellite imagery has progressed, it too has the ability to provide ecological data appropriate to management requirements (Mumby and Green, 2000). For the differentiation of ecological zones across reef tops, the latest digital airborne scanners, e.g., the Compact Airborne Spectrographic Imager (CASI), benefitting from the low-level aircraft platforms of aerial photography and the sophisticated scanning technology of satellites, are now arguably the most effective (Mumby and Green, 2000). Its spectral resolution is at least equal to that of satellite imagery. Spatial resolution is also high though dependent on flying height (e.g., from 840 m it is 1 m). Depth penetration can be >18 m. In a comparison of techniques for mapping reefal habitats, Mumby and Green (2000) quote

**Aerial Photography of Coral Reefs, Figure 3** Color near the infrared photograph of Pandora Reef near Townsville, GBR on a medium low tide. The full tonal range of the IR reflectance is used on the features, which are exposed or have a water cover of ~1 m including living coral margins, shingle ridges, and reef flat pools with depths up to 1 m.

81% accuracy for CASI compared with the levels of 57% for 1:10,000 color aerial photography and <37% for satellite imagery.

Over the last 20 years, the various types of remote sensing have complemented each other. Advances in the analysis techniques for digitized aerial photography has largely come from satellite imagery (see Andrefouet and Riegl, 2004), and sophisticated airborne scanners have combined the advantages of these complementary techniques. Coral reef science has benefitted from remote sensing for almost 100 years. Among all the aerial remote sensing techniques, aerial photography still has the finest resolving power. For example, further experiments by Hopley and Catt (1988) on Cape Tribulation reefs (GBR) used photography from as low as 500' (152 m), producing images with a pixel size of only  $7 \times 7$  cm, sufficient to differentiate between major groupings of corals and other organisms. The main disadvantage is the size of the data bank resulting from the very high resolution. Nonetheless, aerial photography remains an important tool for documenting the physical and ecological complexity of coral reef habitat, especially when the scale and resolution are geared to the specific needs of the project with which it is associated (see also *Remote Sensing*).

## AGASSIZ, ALEXANDER (1835–1910)

---

Eberhard Giscler  
Institut fuer Geowissenschaften, Frankfurt am Main,  
Germany

Alexander Agassiz was born on 17 December 1835 in Neuchâtel, Switzerland. He was the son of the famous naturalist Louis Agassiz. A. Agassiz made a distinguished

career as reef scientist, zoologist, mining engineer, and science administrator in the US (Dobbs, 2005). After receiving a degree in engineering and chemistry, he studied biology at Harvard University from 1865 to 1869. Since 1860, Agassiz had been working at the Museum of Comparative Zoology as an assistant and since 1875 as curator. His field was marine invertebrates and he was especially interested in echinoderms, annelids, cnidarians, and coral reefs. Interestingly, starting in 1865, Agassiz made a second career in mining because he had inherited the Calumet Copper Mine in Michigan. Eventually, he became one of the richest Americans and financed his own research expeditions starting in mid-1870ies, which led him to almost every major reef area on earth. Expeditions went to Florida, the Bahamas, Bermuda, Cuba, the Yucatán, Galápagos, Hawaii, Fiji, Tonga, the Ellice Islands (now: Tuvalu), Marshall Islands, Gilbert Islands, Caroline Islands, the Tuamotus, Cook Islands, Guam, Japan, the Maldives, and the Great Barrier Reef. He published six major monographs on reefs (Agassiz, 1885, 1889, 1894, 1899, 1903a, b) and numerous shorter papers. A summary of his work can be found in two relatively brief but instructive articles (Agassiz, 1900, 1903c). Agassiz was a follower of the Murray (1889) theory proposing that reefs grew from a submarine plateau to the water surface, opposing Darwin's (1842) subsidence theory. He proposed that denudation and submarine erosion can create shallow platforms from which reefs can accrete. For example, the Maldives archipelago was used by Agassiz in support of this model. Some barrier reef lagoons were formed through erosion, e.g., in the Society Islands, Fijis, Carolines, according to Agassiz. He also considered moderate recent uplift as important agent of modern reef formation, e.g., in the Tuamotu archipelago. When summarizing his observations on reefs, Agassiz erred in interpreting exposed limestone as well as shallow submarine rock ledges as remnants of denuded and eroded fossil (Tertiary) limestone. Much later, many of these outcrops and submarine terraces were radiometrically dated and turned out to be of late Quaternary age. Even so, Agassiz's observations on reefs worldwide served as a basis for numerous later studies, and, he critically challenged Darwin's subsidence theory thereby stimulating subsequent research that identified the importance of factors such as erosion and sea-level change for reef development. After being a curator in Harvard for 23 years, Agassiz became the head of the Museum of Comparative Zoology for 10 years. He also served as President of the US National Academy of Science for 6 years (1901–1907). A. Agassiz died on 23 March 1910 aboard a ship sailing from Southampton to New York.

## AIRBORNE DUST IMPACTS

---

Eugene A. Shinn<sup>1</sup>, Barbara H. Lidz<sup>2</sup>

<sup>1</sup>University of South Florida, St. Petersburg, FL, USA

<sup>2</sup>U.S. Geological Survey, St. Petersburg, FL, USA

### Definition

As in the Dust Bowl of the Midwestern United States in the 1930s, arid-soil conditions exist in other countries today. Periodically, ground-level winds associated with high-energy fronts, pick up the soils along with whatever chemical or pollutant may be associated with the source soil and lift them into the troposphere. Wind systems such as the trade winds transport the dust clouds with their exotic components around the globe. Impacts of these airborne dusts are just now being recognized. Many of the non-soil substances such as pesticides are known to be toxic to human health, marine life, and coral reef ecosystems.

### Background

Soil dust (generally less than 10  $\mu\text{m}$  in diameter) containing viable microbes, toxic minerals, radiogenic elements, feces, and modern pesticides may negatively impact corals and coral reef-associated organisms as well as human health and terrestrial ecosystems. Marine impacts from this noxious mix are likely to be most pronounced in pristine clear-water areas, where corals have not previously adapted to stressors such as nutrients, pollution, and sedimentation.

In recent years beginning in 1973, the changing climate and desertification of the North African Sahel region resulted in increased quantities and ongoing transport of soil dust to the Americas (Prospero and Nees, 1986). Shinn et al. (2000) summarized the relation between annual variations in dust flux and coral demise. Iron, the most consistent elemental component of soil dust, after silica, has been shown to stimulate red-tide outbreaks in the Gulf of Mexico (Walsh et al., 2006). Red-tide outbreaks can have devastating effects on coral reefs.

The quantity of soil dust leaving Africa each year has been estimated to be as high as 1 billion tons (D’Almeida, 1986). Hundreds of millions of tons reach Caribbean reefs and the Amazon rainforest annually (Prospero et al., 1996).

### Processes

African dust periodically impacts the entire East Coast of the US and occasionally exceeds Environmental Protection Agency atmospheric-particulate standards in Miami, Florida (Prospero, 1999). African dust has been transported as far west as Carlsbad, New Mexico (Perry et al., 1990). During Northern Hemisphere winters, African dust storms shift southward with the Intertropical Convergence Zone (ITCZ) and are known to be a major supplier of nutrients to the Amazon Basin (Swap et al., 1992).

During Northern Hemisphere summers, the ITCZ shifts northward, creating conditions conducive to dust storms and subsequent transport of dust and adhering contaminants across the Atlantic Ocean. The same weather conditions are responsible for creation of Atlantic hurricane formation, especially the so-called Cape Verde storms that originate late in the season.

African dust storms initiate when strong winds lift soil from dried lakebeds, especially in the Bodele Depression, located in Chad in central Africa (Koren et al., 2006). Once airborne, the dust is carried by trade winds in the troposphere (below 3,000 m) in what meteorologists call the Saharan air layer. Dust clouds leaving northwest Africa typically reach the Americas in 5–7 days. Recent and ongoing studies indicate African dust storms retard or prevent hurricane formation by suppressing raindrop formation and precipitation, while at the same time shading sunlight and cooling sea-surface waters. Dust storms also create hazy days and beautiful sunsets.

Dust-borne winds occur at irregular intervals. Peak formation and transport are associated with positive phases of the North Atlantic Oscillation (NAO). The NAO is the difference between pressure at the Azores High (sometimes called the Bermuda High) and the Icelandic Low. The NAO is dependent on the route and intensity of the trade winds. During positive NAOs, this persistent barometric high drifts eastward, closer to Africa where it alters meteorological conditions and suppresses rainfall. Positive phases of the NAO thus induce droughts. The NAO is also linked, and influenced, by the much larger El Niño

Southern Oscillation (ENSO). The ENSO has worldwide meteorological effects, including increasing wind shear in the subtropical Atlantic that is also known to suppress tropical-cyclone formation.

## Effects

Iron and minerals in African dust form reddish-brown layers in white- to cream-colored carbonate sediments throughout the rock record in Florida and the Caribbean. In modern times, Caribbean corals experienced an unusual onset of disease and demise in the late 1970s that peaked in 1983–1984. The peak coincided with a major ENSO and positive NAO coupled with the largest dust flux at the island of Barbados since monitoring began there in 1965 (Shinn et al., 2000). Significant coral bleaching began in the Pacific in 1982–1983 (Glynn, 1988), followed by widespread Atlantic coral bleaching in 1986–1987, both times of high dust flux. The El Niño of 1998 was also a time of increased dust flux to the Caribbean.

Sporadic fish kills and cases of ciguatera fish poisonings occurred in 1983–1984. Caribbean-wide demise of the herbivorous black long-spined sea urchin *Diadema antillarum* (Lessios et al., 1984) and onset of sea-fan disease caused by the soil fungus *Aspergillus sydowii* also began around that time (Weir-Brush et al., 2004). *Aspergillus sydowii* has been cultured from African dust collected in Mali, Africa. *Aspergillus sydowii* does not reproduce in seawater. These Caribbean-wide die-offs severely impacted reef vitality by allowing algal growth to go unchecked. Whether diseases and bleaching are caused by specific elements or microbes carried by African dust or simple elevation of water temperature is controversial and not well understood. A major problem has been separating effects of dust from those of the rising temperature. Both hypotheses are based mainly on correlation and not on absolute proof, other than the fact that *A. sydowii* is a verified cause of sea-fan disease.

What is known is that viable microbes, bacteria, and fungi are common dust components (Griffin et al., 2003; Griffin, 2007). Shielding of ultraviolet radiation by the dust clouds themselves enables microbes to survive long journeys through the atmosphere. Hundreds of viable species have been cultured and recognized in dust thus far (Kellogg and Griffin, 2006). Of those recognized, about 10% are human pathogens and 30% are plant pathogens (Griffin et al., 2003). Most microbes recovered from dust have not yet been identified.

In addition to viable microbes, toxic metals including mercury and arsenic are also components of dust (Holmes and Miller, 2004; Garrison et al., 2006). Bioassays have shown that copper in African dust is toxic to phytoplankton in near-surface ocean waters and thus affects primary productivity as well as the CO<sub>2</sub> budget (Payton et al., 2009). Human-health effects, first noted by Darwin (1845) while he was aboard the HMS *Beagle*, are well known to Caribbean-island citizens.

## Asian dust

Asian and Australian dusts settle on Pacific and Indian Ocean coral reefs and atolls but effects of those dusts are less well known. Australian dust contains abundant microbes (De Deckker, 2008). In addition, red tides have been reported along the Australian coast following dust events. Satellite imagery shows that Australian dust clouds usually move from the west (Outback region) out over the Great Barrier Reef and eastward toward New Zealand.

Beginning in April, Asian dust clouds often blanket Korea, pass over Japan, and then cross the North Pacific. Iron in Asian dust increases primary productivity in the open Pacific (Young et al., 1991). Asian dust is also the source of soils in the Hawaiian Islands (Chadwick et al., 1999). These dust clouds impact the Western US, Alaska, and the North Sea where the dust stains sea ice. Asian dust has at times blocked the sun in Denver, Colorado, and has been identified, along with African dust, in Alpine snow. Asian dust is widespread, yet there are few published accounts of its toxic components, especially microbes. Clearly, Asian dust transports industrial pollutants as it passes over Chinese factories and coal-fired power plants. The full effects of Asian dust on coral reefs in the Pacific and Indian Oceans are not well known. Investigation of impacts of various airborne soil dusts on coral reefs and other marine organisms is in its infancy.

## Summary

Dust storms are global events. Dusts from Africa, Asia, the Americas, the Middle East, and Australia periodically fill the air with soil particles to which viable microbes, bacteria, fungi, and toxic chemicals are attached. Dusts and their exotic components are transported through the troposphere to be deposited far from their sources. Dusts cause hazy days and spectacular sunsets, but also pose risk to human health (e.g., asthma), marine life (e.g., red tides), and coral reef health (e.g., sea-fan disease). Impacts of airborne dusts on all ecosystems are just beginning to be recognized.

## ALGAE, BLUE-GREEN BORING

---

Mark M. Littler, Diane S. Littler  
 Smithsonian Institution, Washington, DC, USA

## Synonyms

Blue-green microborers/endoliths; Endolithic (euendolithic) cyanophyta/cyanobacteria; Rock-boring blue-green algae

## Definition

The blue-green boring algae are filamentous, prokaryotic, mostly photosynthetic organisms that chemically bore into calcareous rock and limestone.

Penetrating or boring algae play important roles in the bioerosion of coral reefs; these filamentous microorganisms result in the breakdown of carbonate structure both directly and indirectly [see Tribollet (2008) for review]. They occur from the upper intertidal to abyssal depths (Golubic et al., 1984), but, in general, show a decrease with depth. The commonest are blue-green algae (Cyanophyta, Cyanobacteria) that attack calcareous substrates differentially; the aragonite skeletons of corals are most easily penetrated and the denser calcite deposits of coralline algae are most resistant. However, the mechanism of carbonate dissolution remains largely unknown and actually contradicts geochemical models that predict the precipitation of carbonates by photosynthetically induced pH increases. As a consequence of variable processes, such as selective settling, competition, persistence, and subsequent grazing of euendolithic (true endoliths) Cyanobacteria, coastal rocks are biodegraded differentially, resulting in grotesque sharp-edged features called karsts (Figure 1). These processes act as feedback mechanisms by producing diverse microbial habitats with patchy water-retention pockets, which further enhance bioerosion and endolithic community diversity.

Boring endoliths colonize all carbonate substrates on coral reefs and are distributed throughout the world's tropical seas. Intertidal carbonate coasts are most intensively bioeroded (Figure 2). However, endolithic activity not only negatively inflicts damage to living hosts, but also

**Algae, Blue-Green Boring, Figure 1** Example of karsts formed by irregular habitats colonized by boring Cyanobacteria and their deeply rasping predators.

**Algae, Blue-Green Boring, Figure 2** Example of boring blue-green algal intertidal zone mostly undercut by deep-rasping chitons.

can provide positive overall benefits to reefs as well, including important primary productivity yields in otherwise dead substrates. Endoliths attract excavating grazers (Figures 3 and 4), which contributes to massive biodestruction processes and sediment formation. In other words, the bioerosional effect of boring Cyanobacteria alone is secondary; their primary significance is in providing the nutritional base for excavating grazers.

Boring Cyanobacteria have been important in the destruction of carbonate, throughout geological times. Marine limestones can be infiltrated by more than 0.5 million endolithic filaments per square centimeter. The oldest recorded endolithic blue-green was found from 1.5 billion-year-old stromatolite rocks in China (Zhang and Golubic, 1987) – the earliest known occurrence of bioerosion.

**Algae, Blue-Green Boring, Figure 3** Chitons rasping deep holes in the intertidal substrate.

**Algae, Blue-Green Boring, Figure 4** Gastropods taking shelter in sharp karst formed by these excavating grazers.

The diversity of boring micro flora is thought to be large, comprising not only undiscovered blue-green algae, but also including other algae (chlorophytes, rhodophytes) and fungi. Although their taxonomy has been studied for decades, new species are still being discovered, especially following the advent of molecular techniques. However,

the taxonomy and diversity of boring blue-green algae remain relatively unknown.

## ALGAE, CORALLINE

---

Mark M. Littler, Diane S. Littler  
Smithsonian Institution, Washington, DC, USA

## Synonyms

Calcareous Corallinales; Corallines; Coralline algae; Nullipores; Rhodalgal facies (geological term)

## Definition

Coralline algae are heavily calcified red algae of the order Corallinales (Rhodophyta). The plant body (thallus) is composed of chains of cells (filaments) that may fuse laterally or also form secondary (lateral) pit connections. Separate haploid male and female plants produce gametes in sori (spore clusters) or domed single-pored conceptacles, with spores (haploid tetraspores or diploid bispores) being formed in sori that are typically modified into either single-pored or multipored conceptacles.

## Introduction

Coralline algae are important carbonate sediment producers and rank among the major reef builders. Corallines are characterized by a thallus that is stony because of calcareous deposits contained within and between the cell walls. This extensive calcite crystalline form of  $\text{CaCO}_3$  is a major factor determining the geological importance of the group. High preservation potential has produced an excellent fossil record. The colors of these algae are most typically pink or other shade of red, but some species can be variations of purple, blue, gray-green, or brown. Beginning with their discovery in 1707 (Sloane), corallines were thought to be animals. However, in 1837 Philippi recognized that coralline algae were plants and

proposed the two generic names *Lithophyllum* (for flat forms) and *Lithothamnium* (for erect branched forms). However, in an overlooked earlier treatment, Bory de Saint-Vincent (1832) had recognized *Tenarea undulosa* as a crustose calcareous alga, making it the oldest species name originally applied to the coralline algae in a botanical context. For many years, coralline algae were included in the Order Cryptonemiales as the Family Corallinaceae until 1986 (Silva and Johansen) when they were elevated to the Order Corallinales.

## Systematics

The Corallinales is a monophyletic group comprised of three Families (Table 1, Sporolithaceae, Corallinaceae, and Hapalidiaceae). They also comprise two very distinct morphological groups [i.e., geniculate (articulated, segmented, jointed) species and nongeniculate (non-articulated, unsegmented, crustose) species]. Though useful, this traditional separation no longer constitutes a phylogenetic arrangement (Bailey, 1999).

## Life history

Coralline algae are exclusively marine plants and occur throughout all of the world's oceans, where they often cover most of the available hard substrates, being attached by crustose expanses (cellular adhesion) or root-like hold-fasts (haustoria). Many are epiphytic (on other plants) or epizoic (on animals), and some are even endophytic parasites within other corallines. Despite their ubiquity, the coralline algae remain poorly understood by coral-reef scientists, and even by specialist algologists/phytologists. Corallines reproduce by sori, which are specialized volcano-shaped domed conceptacles containing haploid tetraspores, diploid bispores, or either male or female gametes. Gametes fuse to form the parasitic diploid carposporophyte stage within the female conceptacles and the resultant carpospores germinate into diploid tetrasporophytes. Haploid tetraspores germinate to produce the male and female gametophytes. Some crustose coralline populations are unusual in that uninucleate bispores (diploid) are commonly the sole means of reproduction. The plant body (thallus) is composed of strands of pit-connected cells (filaments) that may fuse laterally or also form secondary pit connections. Pit connections and pit plugs are translocational structures characteristic of red algae (Rhodophyta). These reproductive and vegetative structures provide the critical anatomical characters used in coralline algal taxonomy, but also create major obstacles for workers, since complicated decalcification techniques and microtome sectioning of infrequently present cryptic features are required.

Articulated (geniculate) corallines are upright or pendulous branched bushy plants (Figure 1), with shallower and warmer distributions than nongeniculate species. The multiple clumped thalli are flexible due to noncalcified zones (genicula, joints) separating longer

calcified segments (intergenicula). Many articulated and upright crustose corallines can also form extensive two-dimensional adherent crusts, allowing them to spread laterally, thereby providing those species with multiple “bet-hedging” ecological survival strategies (called heterotrichy; Littler and Kauker, 1984). The upright portions receive relatively more light and nutrients, and are faster growing with increased fertility; whereas, horizontal crusts are more resistant to physical forces such as grazing, wave shearing, and sand scouring, while allowing the plants to invade horizontal primary space.

Crustose (nongeniculate) corallines range in thickness from a few micrometers to many centimeters (Figures 2 and 3). The thinner forms are faster-growing early colonizers and occur on all hard substrates and other marine organisms. Crustose corallines span a spectrum of morphotypes from thin sheet-like crusts to thick slow-growing massive pavements to upright branched and columnar coral-like heads that contribute to both cementation and bulk. On oceanic reefs, the highest part of the reef is often a massive “algal ridge” of crustose corallines in the reef’s breaker zone (Dawson, 1961) – see below. Thalli of thicker forms often consist of three recognizable layers: an attached lower hypothallus, a middle perithallus, and an upper epithallus. Trichocytes (hair cells, megacells) occur as horizontal plates within the epithallus layer in some genera such as *Porolithon*. The meristematic (growing) region is usually located as a layer beneath the uppermost intercalary perithallus cells, a feature which is unusual in the Rhodophyta, whose members (except also for Delesseriaceae) typically show strictly apical cell growth. Because of the upright branched head formers (Figure 3), some specialists prefer the term nongeniculate over crustose; however, all have extensive crustose bases and whether branched or simple they are still elaborations of crusts.

### Rhodoliths

In the absence of hard substrates, many nongeniculate species can propagate as free-living rhodolith nodules colonizing sedimentary seafloors (Figure 4). Some of the attached crustose corallines break free and then continue spherical growth as they are tumbled by wave action and bioturbation to ultimately cover vast areas as free-living rhodoliths (= nodules, rhodolites, maërl, red algal balls, algaliths). Rhodolith beds have been found throughout

**Algae, Coralline, Figure 1** Spectrum of articulated (jointed, geniculate) coralline algal forms.

all of the world's oceans. Globally, rhodoliths fill an important niche in marine ecosystems, serving as transitional habitats between rocky substrates and barren sedimentary areas. Under favorable preservation conditions, rhodoliths can be the predominant contributors of carbonate sediments, often forming rudstone or floatstone depositional beds consisting of large fragments of rhodoliths contained in grainy matrices. Although they are rolled by infrequent storms, rhodoliths nevertheless provide a three-dimensional micro-habitat onto which a wide variety of species attach, including other algae, corals, and commercial species such as clams, oysters, and scallops. Rhodoliths are a common feature of modern and ancient carbonate shelves worldwide. Fossil rhodoliths commonly are used to derive paleoecological and paleoclimatic information and rhodolith communities contribute significantly to the global calcium carbonate budget.

Quantitative submersible studies (Littler et al., 1991) of deep-water rhodolith development, distribution,

abundance, and primary productivity, at sites of both active formation and breakdown, provided the following detailed case-study. The 1.27 km<sup>2</sup> upper platform (67–91 m deep) of a ~1,000-m high Bahamian seamount (San Salvador Seamount) averaged 95.8% cover of rhodoliths, contributing an impressive 391 tons of organic carbon per year to deep-sea productivity (tropical storms cause the rhodoliths to roll at this depth). The predominant crustose coralline alga was acclimated to extremely low light ranges, with an extremely narrow PI curve (photosynthesis vs. irradiance) of net primary productivity (0.005 to slightly beyond 0.24  $\mu\text{mol}$  per meter square per sec of photosynthetically active radiation). Horizontal platform areas contained up to five-deep accumulations (about 45 cm thick) of rhodoliths, with their visible planar (two-dimensional) crustose algal cover (68.5%) being composed of 41% *Lithophyllum* sp., 14.9% mixed crustose corallines, and 12.6% *Peyssonnelia* sp. The platform rhodoliths also contained an average 25% cover of the

**Algae, Coralline, Figure 2** Spectrum of simple two-dimensional forms of nongeniculate (crustose) corallines. *Upper right* image shows synchronous sloughing in *Neogoniolithon fosliei*.

foraminiferan *Gypsina* sp.: by contrast, *Gypsina* cover was minimal on the slope rhodoliths. Rhodoliths that had spilled down from the relatively flat platform tended to be concentrated in fan-shaped deposits that were more prevalent near the tops of the slopes. Cover of living crustose algae on the deeper slope rhodoliths averaged only 22.8% and was made up of 14.8% unidentified crustose corallines, 6% *Lithophyllum* sp., and 2% *Peyssonnelia* sp.

Throughout platform depths from 67 to 91 m, rhodoliths were fairly uniform in composition and abundance. They ranged from 4 to 15 cm in diameter, with an average diameter of about 9 cm, and were roughly spherical with smooth living surfaces. The rugose rhodoliths spilling down the steep slopes of the seamount to depths below 200 m were characteristically smaller (mean of about 5 cm diameter), much rougher, and pitted by boring organisms. Cross-sections through the centers of upperplatform nodules showed outer relatively thin (1–3 cm thick) well-preserved envelopes overlying dead laminated crustose layers). These layers surrounded much thicker cores of biotically altered carbonates (comprised mostly of corallines, foraminiferans, and corals) that had been extensively reworked by boring sponges, boring algae, polychaetes, and pelecypods. Radiocarbon dating indicated that the outermost unaltered envelopes beneath actively growing crusts averaged 429 years old (range = 112 to 880 ybp), while the innermost unaltered layers showed a mean age of 731 ybp (200–1,100 ybp).

## Geology and evolution

Crustose coralline algae appeared in the early Cretaceous and have been important components of shallow-marine communities throughout the Cenozoic, mostly showing long-term increases in species richness during much of their history. There are currently over 1,600 described species of crustose coralline algae (Woelkerling, 1988) and ~649 fossil species (Aguirre et al., 2000). Interestingly, Miocene coastal carbonate habitats are characterized by a worldwide bloom of coralline red algal deposits (termed rhodalgal facies). These extensively developed facies (i.e., characteristic sedimentary deposits) temporarily replaced corals throughout the tropics and subtropics as dominant carbonate producers (e.g., Esteban, 1996). By calibrating modern carbonate assemblages to local oceanographic conditions in the Gulf of California, Halfar et al. (2004) demonstrated that the predominance of rhodalgal facies occurred under mesotrophic to slightly eutrophic conditions. In the Mediterranean region, early to middle Miocene carbonates contain more rhodalgal components than coral-reef deposits (Esteban, 1996). In addition to being widespread globally, fossil coralline algae also exhibited their greatest species richness during the early and middle Cenozoic (early Miocene peak of 245 species; Aguirre et al., 2000), with a collapse to a late Pleistocene low of 43 species. In reviewing 37 representative late Pliocene studies, Halfar and Mutti (2005) concluded that although rhodalgal facies were clearly the dominant components at specific study sites, they often were not

**Algae, Coralline, Figure 3** Spectrum of head-forming crustose corallines with upright branched excrescences.

**Algae, Coralline, Figure 4** Examples of coralline algal rhodoliths.

emphasized as extensively as the much better-known coral assemblages. A number of the above studies focused mainly on coral-reef components; whereas, rigorous reanalyses of the facies studied actually indicated a relatively low percentage of corals and a predominance of rhodoliths. Esteban (1996) noted a similar bias in

a review of Miocene Mediterranean coral reefs and rhodalgal facies. Such discrepancies can be attributed mostly to poor knowledge of coralline red algae and rhodolith facies, in conjunction with the tendency for workers to apply classic coral-reef depositional models, even in settings where corals were sparse.

Throughout the world's oceans, during the late/early to early/late Miocene, while many phototrophs declined globally, coralline red algae radiated and diversified greatly. In fact, corallines have shown a long-term overall increase in species richness throughout most of their history. Despite this, coralline species diversification was not sustained after the Miocene (Aguirre et al., 2000) and coralline algae suffered a series of extinction events, each of which eliminated at least 20% of the species. In fact, during the two largest extinction events of the late Cretaceous and late Miocene-Pliocene, about 66% of all coralline species were lost. Each extinction event was followed by substantial episodes of rapid radiation and speciation, particularly in the early Paleocene and Pleistocene.

The conspicuous Miocene shift from coral- to rhodolith-dominated carbonate communities has been attributed to global climate changes. Halfar and Mutti (2005) argued that the prevalence of rhodolith facies, which developed under broader nutrient and temperature ranges than did the coral-reef facies, was initially triggered by a global enhancement of nutrient resources. In the middle Miocene, nutrient availability was apparently augmented by increased upwelling- and erosion-related nutrient inputs into coastal ecosystems. These nutrient increases together with declining temperatures, following the early to middle Miocene climatic optimum, led to further expansion of rhodalgial facies. Hence, a global phase shift occurred in nearshore shallow-water carbonate producers from corals to domination by coralline species that were tolerant of the higher levels of nutrification. Geological deposits of coralline algae contain organic carbon compounds such as cellulose (due to photosynthesis) as well as massive calcareous compounds due to calcification (precipitation of inorganic  $\text{CaCO}_3$ ). The resultant carbon stores may be among the most important in the biosphere as neutralizers of global oceanic acidification and as reservoirs of excess greenhouse  $\text{CO}_2$ .

A striking geological pattern is the occurrence of an inverse relationship in the species richness of two of the families of Corallinales. From the Cretaceous to Pleistocene, Corallinaceae (both warm- and cold-water species) increased, while the tropical Sporolithaceae declined. This climatic link was supported for Sporolithaceae and Corallinaceae by both direct and inverse correlations, respectively, between species diversity and documented Cretaceous to Cenozoic paleotemperatures. Although, remaining to be more firmly established, coralline diversification since the Cretaceous (Steneck, 1983, 1985) may have been driven by simultaneous coevolutionary increases in herbivores (mainly limpets, echinoids, and grazing fishes) that physically scrape and remove fleshy algal competitors.

### Distribution patterns and functional significance

Crustose (nongeniculate) coralline algae occur worldwide from polar to tropical regions, reaching their highest

diversity in tropical reef environments. Three subgroups of Corallinales show characteristic distributions (Aguirre et al., 2000): (1) Sporolithoideae, low latitude/mainly deepwater; (2) Melobesioideae, high latitude/shallow waters to low latitude/deep waters; and (3) Lithophylloideae/Mastophoroideae, mid to low latitude/shallow waters.

The abundant occurrence of crustose corallines (and corals) in Indo-Pacific reefs was initially recognized by Darwin (1842); however, their important role as reef builders was first emphasized by Agassiz (1888). Most often, corals (Cnidaria) supply the bulk building blocks; whereas, coralline algae do much of the cementing together of debris. Barrier, fringing, and atoll reefs are complex ecosystems that depend on calcareous coralline algae for the development and maintenance of wave-resistant outer fronts (Figure 5). The crustose coralline algae, which deposit a type of calcium carbonate (calcite limestone) that is harder and denser than the aragonite of corals, build this raised "algal ridge" (Dawson, 1961). The intertidal outer algal-ridge habitat, in which crustose

**Algae, Coralline, Figure 5** An example of a well-developed algal ridge from windward Guam, with close-up of the head-forming *Lithophyllum kotschyianum* and the pink crustose *Hydrolithon* (*Porolithon*) *onkodes*.

corallines (mainly species of *Hydrolithon*/*Porolithon*) are crucial in constructing the framework, characterizes surf-pounded windward coral reefs of tropical Indo-Pacific and, to a lesser extent, Atlantic regions. The Pacific algal-ridge builder, *Hydrolithon* (*Porolithon*) *onkodes*, fixes a remarkable 3.2 mg of organic carbon per square meter per hour and 1.9 mg Ca per square meter per hour during an average daylight day (Littler, 1973). The algal ridge by extending above the waterline absorbs tremendous wave energy, not only protecting coastal shorelines that would otherwise erode, but also sheltering the more delicate corals and other reef organisms. Algal ridges develop intertidally and, therefore, require intense and persistent wave action to form, so are best developed on windward areas where there are consistent trade wind conditions.

Some of the coralline algae that develop into shelf-like, thick knobby, or upright branched crusts provide microhabitats for countless vulnerable invertebrates that would otherwise suffer increased mortality due to fish predation (Figure 3). Coralline algae also constitute a food source in the energy webs of coral reefs. Sea urchins, parrotfishes, surgeonfishes, limpets, and chitons all readily feed on coralline algae, which are usually not destroyed due to sunken intercalary meristems that replenish the upper damaged areas. Crustose corallines accelerate colonization by chemically attracting/facilitating the survival of coral larvae (Harrington et al., 2004), as well as the larvae of certain grazing invertebrates. This is adaptive for the corallines because the herbivores then remove epiphytes that might preempt available light or otherwise smother

the crusts. Because of their stony texture, indigestible acid-neutralizing  $\text{CaCO}_3$ , and covered intercalary meristematic layer, corallines are uniquely resistant to considerable levels of grazing. As examples, the most common Indo-Pacific crustose coralline, *Hydrolithon* (*Porolithon*) *onkodes*, often forms an intimate interrelationship with the chiton *Cryptoplax larvaeformis* (Littler and Littler, 1999), as does the Atlantic coralline *H. pachydermum* and the chiton *Choneplax lata* (Littler et al., 1995). The chitons live in burrows that are overgrown by *Hydrolithon*/*Porolithon* and graze nocturnally on the surfaces of the corallines (Figure 6). The pattern of grazing causes rapid meristematic differentiation and redirection in which the interaction produces an abundance of vertical blade-like lamellae, resulting in a spectacular growth form (resembling “castles”). This type of relationship is unique in the marine environment – whereby, the predator actually increases the biomass, surface area, and reproductive capacity (i.e., fitness) of its principal prey (Littler et al., 1995).

### Pathogens

Instances of coralline algal pathogens were unknown until 1993, when CLOD (Coralline Lethal Orange Disease) was first discovered (Littler and Littler, 1995) on Aitutaki Atoll, Cook Islands (Figure 7). The occurrence of CLOD at 25 Great Astrolabe, Fiji sites increased from 0% in 1992 to 100% in 1993, indicating that the pathogen was in an early stage of virulence and dispersal. The bright orange bacterial pathogen grows as fan-shaped to circular bands at a mean linear rate of increase of 1.5 mm per day,

**Algae, Coralline, Figure 6** Castle forms of the crustose corallines created by their association with herbivorous chitons (*Hydrolithon pachydermum*/*Choneplax lata*, left and upper; *H. onkodes*/*Cryptoplax larvaeformis*, lower right).

totally consuming host corallines that are left in its wake. All species of articulated and crustose species tested to date are easily infected by CLOD and it has now spread to become circumtropical throughout all coral-reef habitats. In recent years, a white version of CLOD-like pathogen has become even more abundant worldwide, in addition to the recently recorded dispersion of a virulent black fungal pathogen (Figure 8) of coralline algae first

found in American Samoa (Littler and Littler, 1998) and an unknown species of “target-shaped” coralline pathogen (Figure 9), first reported from the Great Astrolabe Reef (Littler et al., 2007).

### Summary

Coralline algae occupy the entire depth range inhabited by photosynthetic organisms; from upper-intertidal regions

**Algae, Coralline, Figure 9** In situ images of Target Pathogen in the Pacific.

to depths as great as 274 m (Figure 10, Littler and Littler, 1994). The great abundances of corallines in the poorly known deep-sea realm underscore their widespread contributions to productivity, the marine food web, sedimentology, and reef biogenesis in clear tropical seas. The diversity of coralline algal forms is astonishing, ranging from small filamentous strands to some of the larger and most beautiful head-forming organisms on coral reefs

**Algae, Coralline, Figure 10** Rock taken by submersible from >200 m off San Salvador Seamount, Bahamas showing the deepest crustose coralline.

(Figures 1–3). The predominant members of this functional indicator group (Littler and Littler, 2007) tend to be slow-growing competitively subordinate taxa abundant in most reef systems. As a indicator group they are functionally resilient and able to expedite the recovery/restoration of a particular coral-reef system relatively quickly, given that some thin forms of crustose coralline algae accelerate colonization and chemically attract and facilitate the survival of coral larvae (Harrington et al., 2004); whereas, the other two fleshy-algal functional indicator groups (i.e., turfs, macroalgae) tend to overgrow and inhibit coral settlement and survival. Because most crustose coralline algae continually slough-off upper surface layers (Figure 2), they play a key role in physically preventing the settlement and colonization of many fleshy fouling organisms on coral reefs (Littler and Littler, 1997).

Crustose corallines, because of their slow growth, tolerate a wide-range of nutrient levels and generally are conspicuous, but not as predominant as corals, under low concentrations of nutrients and high levels of herbivory (Littler and Littler, 2007). Accordingly, they do well in the presence of both low and elevated nutrients [i.e., most are not inhibited by nutrient stress and many are maintained competitor-free by surface cell-layer shedding (Johnson and Mann, 1986), even at lower levels of grazing (Littler and Littler, 1997)]. Therefore, crustose coralline algae do not require elevated nutrients as might be inferred

(Littler and Littler, 2007); instead, the degree to which they rise to dominance is largely controlled indirectly by the factors influencing the abundances of other functional groups, primarily the corals and fleshy macroalgae. The key point is that crustose corallines dominate mainly by default (i.e., under conditions of minimal competition), where corals are inhibited (e.g., by elevated nutrients or by strong wave action), and where fleshy algae are removed by intense herbivory. The wave-pounded intertidal algal ridges are built predominantly by *Porolithon* (*Hydrolithon*) *onkodes*, *P. gardineri*, *P. craspedium*, and *Lithophyllum kotschyannum* in the Indo-Pacific and *P. pachydermum*, and *L. congestum* in the Atlantic; all are coralline species that appear uniquely tolerant of aerial exposure. The transition from frondose- to turf- to coralline-algal communities has been reported (Steneck, 1989) to closely correlate with increasing herbivory gradients on coral reefs.

In addition to their protective reef-building nature, coralline algae provide a number of other goods and services. Since the eighteenth century, unattached corallines (maërl) have been harvested as acid-soil pH conditioners. In Britain and France, hundreds of thousands of tons of *Phymatolithon calcareum* and *Lithothamnion corallioides* continue to be dredged annually. Enormous maërl beds, several km<sup>2</sup> in area, mainly composed of species belonging to the genera *Lithothamnion* and *Lithophyllum*, are present off the coast of Brazil and have begun to be commercially harvested. Maërl is also used as a mineral food additive for cows, hogs, and other livestock, as well as in the filtration and neutralization of acidic drinking water. Corallines are used in modern medical science in the preparation of dental bone implants (Shors, 1999). The cellular carbonate skeleton provides an ideal matrix for the adherence and regeneration of bone and tooth structures. Coralline algal fossils have proven to be extremely beneficial in deriving paleoecological and paleoclimatic information, and also have been employed as stratigraphic markers of particular significance in petroleum geology. As a spectacularly colorful component of live rock for the flourishing marine aquarium trade, coralline algae are highly desired for their architectural and attractive aesthetic qualities. However, the most important contribution of coralline algae worldwide may well prove to be in ameliorating the greenhouse carbon dioxide buildup associated with global climate change. It is the balance between calcification and respiration – which produce carbon dioxide – and the consumption of CO<sub>2</sub> by photosynthesis that will determine whether corallines act as a “sink” (absorbing CO<sub>2</sub>) or as a source of CO<sub>2</sub>. Experiments that studied how various calcifying systems take up and give off carbon dioxide have shown that the rise in CO<sub>2</sub> produced by calcification is mitigated by its removal through increased photosynthesis (Ohde, 1995; Iglesias-Rodriguez et al., 2008), with a net effect that is unlikely to either contribute greatly or significantly reduce the rise in atmospheric CO<sub>2</sub>. However, rising levels of CO<sub>2</sub> and concomitant acidification of seawater inhibit all

reef builders, including coralline algae (Kleypas et al., 1999). By binding vast accumulations of CaCO<sub>3</sub> during calcification and photosynthesis, corallines may play a role in slowing future acidification of marine habitats such as coral reefs.

## ALGAE-MACRO

---

Mark M. Littler, Diane S. Littler  
 Smithsonian Institution, Washington, DC, USA

## Synonyms

Macroalgae; Macroscopic algae; Multicellular photosynthetic cryptogams; Seaweeds

## Definition

Macroalgae are multicellular marine plants that are easily observed by the unaided eye and whose “thallus” (plant body) is characterized by holdfasts for attachment, and by “laminae,” reproductive “sori,” gas bladders, and/or stipes. They lack the various structures that characterize higher plants, such as true leaves, roots, and encased reproductive organs.

## Introduction

Macroalgae (“seaweeds”) belong to either one of three groups of eukaryotic algae: the Rhodophyta (red algae), Chlorophyta (green algae), and Phaeophyceae (brown algae) or to the prokaryotic colony-forming Cyanobacteria/Cyanophyta (blue-green algae). These four groups do not have a common multicellular ancestor (i.e., collectively they are polyphyletic); although, their chloroplasts – common to all – appear to have had a single blue-green algal (Cyanobacteria) origin. The presence of chloroplasts and subsequent capacity for photosynthesis give marine macroalgae an ecological role as primary producer that is similar to other marine plants, notably “seagrasses.” However, seagrasses are not seaweeds; rather, they are rooted, flower, and seed-bearing “higher” plants (Angiosperms).

The macroalgal thallus (i.e., plant body) consists of blades (leaf-like lamina), reproductive sori (spore clusters), gas bladders [flotation organs (on blades in rockweeds, between lamina and stipes in kelps)], stipes [stem-like structures (may be absent)], and holdfasts [with or without haptera (finger-like extensions anchoring to substrates)]. The stipe and blade combined are known as the frond.

Macroalgae grow attached to stable substrata in seawater (or brackish water) under light levels sufficient for photosynthesis. Seaweeds are most commonly found in shallow waters on rocky shores; however, the green algal group Bryopsidales includes rhizoidal forms adapted

to proliferating in sedimentary environments. At the shallowest level are algae that inhabit the high-intertidal spray zone, whereas, the deepest living forms are attached to the seabed under nearly 295 m of water (Littler and Littler, 1994; see *Algae, Coralline*, Figure 10). The deepest macroalgae are calcified crustose coralline species.

### Human utilization of macroalgae

Macroalgae have a variety of uses. They are used extensively as food by coastal cultures, particularly in Southeast Asia. Seaweeds are harvested or cultivated for the extraction of alginate, agar, and carrageenan – gelatinous substances collectively known as hydrocolloids or phycocolloids. Colloids have great commercial importance, especially in the production of food additives. The gelling, water-retention, emulsifying, and other physical properties of colloids are critical to the food industry. Agar is used in foods such as candies, canned meats, desserts, bottled drinks, and gelatin molds. Carrageenan is used in the manufacture of salad dressings, condiments, dietary foods, as preservatives in canned meat and fish, milk products, and bakery goods. Alginates are utilized for many of the same uses as carrageenan, but are also used in the production of paper sizings, glues, colorings, gels, explosive stabilizers, fabric prints, hydro-spraying, and drill lubricants. Macroalgae have long been used as fertilizers and soil conditioners. Seaweeds are currently being investigated as sources of biodiesel and biomethane. Algal extracts are also widely used in tooth-pastes, cosmetics, and paints.

In the biomedical and pharmaceutical industries, alginates are used in wound dressings and production of dental molds. In microbiological/diagnostic research, agar

is extensively used as the culture substrate of choice. Seaweeds are also a source of iodine, an element necessary for thyroid function. The vast array of natural products that algae produce represents a potential “gold mine” of medicinal compounds that are still yielding promising results.

### Ecological significance of macroalgae

Top-down control of macroalgae by abundant populations of large mobile herbivores is particularly well studied for coral reefs, beginning over four decades ago with the caging study of Stephenson and Searles (1960). As examples, Sammarco et al. (1974), Ogden and Lobel (1978), Sammarco (1983), Carpenter (1986), Lewis (1986), Morrisson (1988), and numerous other workers (see review by McCook et al. (2001)) have demonstrated that lowering herbivory without increased nutrient inputs (usually assumed) mostly results in rapid increases in fleshy algae. However, when coral reefs are exposed to an increase in nutrients (bottom-up), fleshy macroalgae (Figure 1) may be favored over the slower growing but highly desirable corals (Lapointe et al., 1997). On healthy oligotrophic coral reefs, even very low nutrient increases may exceed critical levels that can shift relative dominances by stimulating macroalgal production, while inhibiting corals (Littler and Littler, 1984). Interestingly, large biomasses/standing stocks of slow-growing perennial macroalgae (e.g., rockweeds) can develop given sufficient time, even under low inorganic nutrient concentrations (McCook, 1999). Also, *Sargassum* spp. can coexist with corals in oligotrophic waters by utilizing particulate organic sources of nutrients (Schaffelke, 1999). Therefore, in this context, large macroalgal biomasses do not

Algae-Macro, Figure 1 Images of frondose macroalgae overgrowing corals.

necessarily require or indicate detrimentally abundant dissolved nutrients.

Fleshy macroalgae can outcompete corals (Birkeland, 1977; Bellwood et al., 2006), many of which are inhibited under elevated nutrient levels (reviewed in Marubini and Davies, 1996). Fast-growing macroalgae are opportunists that benefit from disturbances that release space resources from established longer-lived organisms. They can also take over space from living corals (Birkeland, 1977) when provided with sufficient nutrients. As a result, frondose macroalgae (those that form carpets of horizontal thalli) are generally recognized as harmful to coral reefs due to the linkage between excessive blooms and coastal eutrophication (ECOHAB, 1997). The competitive dominance of fast-growing macroalgae is inferred from their overshadowing canopy heights, as well as from inverse correlations in abundances between algae and other benthic producers (Lewis, 1986), particularly under elevated nutrient concentrations (e.g., Littler et al., 1993; Lapointe et al., 1997). Macroalgae, such as *Halimeda* spp. (Figure 2), also can gain competitive advantage by serving as carriers of coral diseases (Nugues et al., 2004). The fleshy macroalgal form-group has proven to be particularly attractive to herbivores (see Hay, 1981; Littler et al., 1983a, b) and only becomes abundant where grazing is lowered or swamped by excessive algal growth [chemically defended forms such as Cyanobacteria (Figure 3; Paul et al., 2007) are exceptions]. Overcompensation by high levels of herbivory may explain some of the reported cases (e.g., Smith et al., 2001) of specific corals surviving high-nutrient coral-reef environments.

### Major macroalgal groups

#### Rhodophyta (red algae)

Rhodophyta are generally some shade of red, the result of having large quantities of the red pigment phycoerythrin

in their photosynthetic cells. This red pigment in combination with various other pigments is responsible for the vast array of colors ranging from translucent pale pink, lavender, purple, maroon, burgundy to iridescent blue (Figure 4), but generally with some hint of red. The pigment phycoerythrin is water-soluble; therefore, red algae immersed in hot water will stain the liquid red or pink and the thalli will eventually turn green. Other red-algal characters are eukaryotic cells lacking motile gametes (without flagella and centrioles), floridean starch as the food reserve, and chloroplasts containing unstacked thylakoids without an external endoplasmic reticulum. Pit connections and pit plugs are unique and distinctive features of red algae that form during the process of cytokinesis following mitosis. Most red algae are also multicellular, macroscopic, marine, and have sexual reproduction. They display alternation of life-history phases including a gametophyte phase and two sporophyte phases.

The red algae are almost exclusively marine and comprise the most diversified and the largest group of tropical reef plants, with estimates of up to 10,000 species. Their diversity of forms is astonishing, ranging from small filamentous turfs to some of the larger and most beautifully delicate organisms on coral reefs (Figure 4). Calcareous red algae can dominate some reefs and often surpass corals in reef-building importance [e.g., *Porolithon* (*Hydrolithon*) *craspedium*, Figure 5]. Most often, corals (Cnidaria) supply the bulk building blocks, whereas, coralline algae do much of the cementing together of debris. The crustose coralline algae [forms that deposit a type of calcium carbonate (calcite limestone) that is harder and denser than the aragonite of corals] also build the “algal ridge” (see *Algae*, *Coralline*, Figure 5). The raised algal ridge, by absorbing tremendous wave energy, not only protects land masses that would otherwise erode, but also shelters the more delicate corals and other reef organisms.

Algae-Macro, Figure 3 *Lyngbya polychroa*, a chemically defended blue-green alga overgrowing *Millepora*.

**Algae-Macro, Figure 4** Array of different forms and colors of red algae.

### Phaeophyceae (brown algae)

The most frequent color within Phaeophyceae is some shade of brown, from pale beige to yellow-brown to almost black. This color is the result of large quantities of the brown pigment fucoxanthin. Fucoxanthin is alcohol soluble and the liquid will turn brown after immersion of a specimen, with the thallus eventually becoming green. They have cellulose walls, with alginic acid and fucoidin also important components. Brown algae are unique among macroalgae in developing into multicellular forms with differentiated tissues, and they reproduce by means of motile flagellated spores. Most brown algae have a life history that consists of an alternation between morphologically similar haploid and diploid plants. *Scytosiphon lomentaria* alternates between four distinct morphological generations, which is considered to be a “bet-hedging” survival strategy (Littler and Littler, 1983).

The Phaeophyceae comprise about 2,000 species and are almost exclusively marine algae and, as kelps (Laminariales), attain their greatest abundance, size, and diversity in cold temperate to polar waters. They occur from the high intertidal (Fucales) to 115 m deep (*Sargassum hystrix*, Littler and Littler, 1994). Tropical brown algae include microscopic filaments, sheets, coarsely branched, and crust forms. Nearly all brown algae have fine (microscopic) hairs emanating from their surfaces that may serve to increase surface area for nutrient uptake.

Brown algae are also well represented and very important on coral-reef ecosystems, with certain species of rockweeds able to dominate the fleshy algal biomass in

back-reef areas. For example, *Sargassum* and *Turbinaria*, growing just behind the reef crest, can form small-scale forests up to several meters high that provide biomass, habitat, and shelter for numerous fishes and invertebrates. Interestingly, we have observed vast drifting rafts of floating *Sargassum* in Fiji that were reminiscent of the Atlantic Ocean’s Sargasso Sea accumulations.

### Chlorophyta (green algae)

The most representative color of the Chlorophyta is some shade of green, the result of having large quantities of predominantly green chlorophyll pigments. Chlorophyll is also present in all of the other algal divisions; however, members of those groups have additional pigments that often overshadow and mask the green chlorophyll color. The green algae, in addition to chlorophylls *a* and *b*, also contain various subordinate carotenoid and xanthophyll pigments. The green algae, with upwards of 7,000 species, are the ancestral relatives of vascular plants (grasses, trees, seagrasses, etc.), which also contain these same basic pigments. Green seaweeds range from microscopic thread-like filaments to thin sheets, while others are spongy, gelatinous papery, leathery, or brittle in texture, ranging to 1.5 m in length (Figure 6). The green algae store their energy reserves as starch; therefore, a drop of potassium iodide (tincture of iodine) on a branch or blade will stain blue-black (iodine is taken up by starch granules). All produce flagellated spores and gametes giving them the advantage of motility.

**Algae-Macro, Figure 5** The reef-building calcareous macrophyte *Porolithon* (*Hydrolithon*) *craspedium*.

Green algae are always present on tropical coral reefs and lagoon floors, often intermixed among seagrass shoots. These are the siphonaceous (giant-celled) forms of Bryopsidales, such as *Halimeda*, *Avrainvillea*, *Udotea*, and *Caulerpa* that employ a unique cytoplasmic streaming/blade abandonment mechanism to eliminate epiphytes (Littler and Littler, 1999). Most Bryopsidales have a rhizophytic “rooted” growth form and readily take-up pore water nutrients by cytoplasmic streaming (Williams, 1984). The deepest occurring fleshy upright alga (*Rhipiliopsis profunda*) is a member of this group and was found by submersible attached to bedrock at a depth of 210 m (Littler and Littler, 1994). Some genera of filamentous or sheet-like green algae are extremely tolerant of stressful conditions and can be indicators of fresh-water seeps, recently disturbed areas (as early colonizers of newly exposed substrates), habitats of low herbivory (high herbivory eliminates palatable greens), and especially areas with an overabundance of nutrients (e.g., bird roosting islands, polluted areas).

Calcified green algae are major contributors to the production of marine sediments. Some genera, such as *Udotea* and *Penicillus*, produce enormous amounts of fine silt and

other sediments due to continual sloughing and following disintegration. In many tropical locales, the sparkling white sand beaches are mostly bleached and eroded calcium-carbonate (aragonite) skeletons of *Halimeda*. “*Halimeda* hash” (i.e., the coarse oatmeal-like accumulations of *Halimeda* segments, Figure 7) has been used in power-generating plants and other fossil-fueled industries as smoke-stack scrubbers/neutralizers to precipitate sulfuric acid and other precursors to acid rain.

### Cyanobacteria (blue-green “algae”)

This ancient, highly controversial, and difficult group is a “prokaryote,” not a true plant. The Cyanobacteria were the first group to evolve photosynthesis, the process that powers the biological world. On tropical reefs, they comprise masses of microscopic organisms that are strung together into large filamentous clumps or colonies (Figure 8). In life, most of these large aggregations have distinctive colors, shapes, or growth forms that provide distinctive recognition features. However, these are lost in preserved specimens, and thus went unappreciated by earlier museum/herbarium-bound taxonomists. Most commonly, the color of blue-green algae is some peculiar shade of pink to purple to black – a combination of red from the pigment phycoerythrin, blue from phycocyanin, and green from chlorophyll.

Colonies may form filamentous tufts, sheets, or globular spheres (Figure 8). Some filamentous colonies show the ability to differentiate into several specialized cell types: vegetative cells (the normal, photosynthetic cells that are formed under favorable growing conditions), akinetes (the stress-resistant long-lived spores that form when environmental conditions become harsh), and thick-walled heterocysts, which contain the enzyme nitrogenase for nitrogen fixation (see below; Herrero and Flores, 2008). Heterocysts also form under specific environmental conditions (anoxia, hypoxia) or where nitrogen is limiting. Many Cyanobacteria also form motile reproductive filaments called hormogonia that glide free from the parent colony at special weaker cells (necridia) and disperse to form new colonies.

Like the other groups of seaweeds, excessive standing biomass of Cyanobacteria is usually considered detrimental to the health of coral-reef systems and people. They produce chemical compounds that can be toxic to fish, plankton, and invertebrates. For example, swimmers’ itch, a skin irritation that beach goers commonly experience, is caused by blooms of the blue-green alga *Lyngbya majuscula* (Figure 9). Black-band disease of corals (Figure 10), found throughout all tropical oceans, is caused by blue-green algae and associated microorganisms (Ruetzler et al., 1983). Certain Cyanobacteria produce neurotoxins, hepatotoxins, cytotoxins, and endotoxins that can be dangerous to animals and humans (Paul et al., 2007). Several cases of human- and many cases of livestock-poisoning have been documented.

The nitrogen fixing capacity of some blue-green algae is extremely important, although often overlooked.

**Algae-Macro, Figure 6** Array of different green algal forms.

**Algae-Macro, Figure 7** *Halimeda* "hash"; i.e., dead calcareous segments.

Heterocyst-forming species bind nitrogen gas into ammonia ( $\text{NH}_3$ ), nitrite ( $\text{NO}_2^-$ ), or nitrate ( $\text{NO}_3^-$ ) that can be absorbed by all plants. This role is crucial for tropical reef systems and especially nutrient-depauperate atoll reefs, which are extremely low in "fixed" nitrogen. Some of

these organisms contribute significantly to global ecology and the oxygen cycle. For example, the marine cyanobacterium *Prochlorococcus* (0.5–0.8- $\mu\text{m}$  diameter spheres) accounts for >50% of the total photosynthetic production of the open ocean and 20% of the planet's atmospheric oxygen (Partensky et al., 1999). Cyanobacteria are the only group of organisms that are able to reduce nitrogen and carbon in aerobic conditions, a feature that may be responsible for their evolutionary and ecological success.

Blue-green algae are abundant worldwide and ubiquitous on coral reefs, where they often occur under extreme environmental conditions. The universally present black band in the splash zones that make rocks or boat ramps slippery is a layer of microscopic blue-green algae. Such blue-greens can withstand exposure to severe drying, extreme salinity, rain water, bright sun, and high heat and still flourish. Cyanobacteria are the oldest known life forms on earth. Stromatolites containing fossilized oxygen-producing Cyanobacteria date to 1.5 billion years ago (Zhang and Golubic, 1987). The ability of Cyanobacteria to perform oxygenic photosynthesis is thought to have converted the early reducing atmosphere of Earth into an oxidizing one. Chloroplasts – the organelles responsible for photosynthesis in all higher plants and eukaryotic algae – evolved from Cyanobacteria via endosymbiosis.

**Algae-Macro, Figure 8** Array of different blue-green algal forms.

**Algae-Macro, Figure 9** Raft of the noxious blue-green alga, *Lyngbya majuscula*.

This evolutionary step dramatically changed the composition of life forms on Earth, triggering an explosion of biodiversity and leading to the near-extinction of oxygen-intolerant organisms.

### Summary

Marine macroalgae are among the oldest and most significant inhabitants of coral reefs. Because of the rapid degradation of tropical reefs worldwide, it is imperative that the role and diversity of macroalgae be studied in a timely,

**Algae-Macro, Figure 10** The black-band disease, *Phormidium corallyticum*, attacking a brain coral.

efficient, and scientifically verifiable manner. It is of paramount importance to characterize the world's coral-reef environments and to understand the responses of these foundation species. The fleshy macroalgal forms are the food of herbivores, and only become abundant when their rate of production exceeds the capacity of herbivores to consume them. On healthy oligotrophic coral reefs, even very low nutrient increases may shift relative dominance from corals to macroalgae by both stimulating macroalgal

production and inhibiting corals (Marubini and Davies, 1996). As a result, frondose macroalgae as a group are generally recognized as harmful to the longevity of coral reefs due to the linkage between excessive blooms and coastal eutrophication.

Reef plant complexity has evolved along very different evolutionary lines. The range of sizes, shapes, life histories, pigments, and biochemical and physiological pathways is remarkable. The biodiversity of coral-reef plant life is unequalled. Macroalgae from four evolutionary lines dominate and, in conjunction with coelenterate corals, are the major primary producers and builders of coral-reef habitats and carbonate architecture. Previously, marine plants have been understudied on coral reefs. However, their rapid growth and short generation time make them ideal subjects for experimental studies. Some are commercially valuable and/or preferred table fare for many humans. Marine plants are essential to the world's biogeochemical cycles and serve as potentially important sources of pharmaceuticals. The critical role that seaweeds play in reef ecosystems overlaps with other fields of marine sciences, such as fisheries resources, marine chemistry, ecology, geology, and coral-reef conservation.

## ALGAE, TURF

Mark M. Littler, Diane S. Littler  
 Smithsonian Institution, Washington, DC, USA

### Synonyms

Algae turfs; Algal mats; Low-growing algae; Prostrate algae

### Definition

Algae turfs are sparse to thick mats of diminutive and juvenile algae less than 2 cm high.

Turf communities ([Figure 1](#)) are composed of juvenile macroalgae and faster-growing filamentous species

accompanied by the ubiquitous blue-greens, diatoms, and detrital sediments. These juvenile and microalgal species assemblages have a high diversity (>100 species in some western Atlantic turfs), although only 30–50 species commonly co-occur at any one time.

Turf algal assemblages, when viewed as a functional indicator group (Littler and Littler, 2007), remain relatively stable year round. They are often able to recover rapidly after being partially consumed by herbivores. Algal turfs characteristically trap ambient sediments and smother corals and other competitors for space by gradual encroachment. Domination by turf algae suggests not only desirably low nutrient levels (bottom-up) but also an inadequate herbivory (top-down) component required for healthy coral-dominated reefs (Littler et al., 2006). Algal turfs have been shown to form extensive horizontal mats under reduced nutrient-loading rates (Fong et al., 1987) or infrequent nutrient inputs (Fujita et al., 1988). Their relatively small size and rapid regeneration from basal remnants (perennation) results in only moderate losses to herbivory at low grazing pressures.

Turf algal community structure can be affected by the behavior of territorial damselfish. Because of their preferential grazing and protection (chasing off of larger herbivores), damselfish cultivate more diverse alga turfs that have higher biomass within their territories. Turf algae have opportunistic (“weedy”) life-history characteristics, including high surface area to volume ratios and the ability to maintain substantial nutrient uptake and growth rates

**Algae, Turf, Figure 1** Examples of naturally occurring algal turf communities. Upper left: *Asparagopsis taxiformis* Sporophyte. Upper right: *Gelidiopsis intricata*. Lower left: *Wurdemannia miniata*. Lower right: *Oscillatoria rosea*.

under low-nutrient conditions (Rosenberg and Ramus, 1984). Turfs also contain populations of nitrogen-fixing Cyanobacteria (Adey, 1998) that can enrich the other low-growing members within the dense turf community in oligotrophic waters.

## ALGAL RIMS

---

Jacques Laborel  
Université de la Méditerranée, Marseille Cedex 9, France

## Definition and morphology

Algal rims are marine biogenic formations of various size and shape, generally edificated by Coralline algae associated with other organisms, developing upon the windward edge of coral reefs or rocky coasts in tropical and subtropical seas.

Thin reef-like structures (often referred to as biostromes) may develop on the outer edge of reef-flats or rocky windward coasts submitted to strong surf, both in tideless or tidal areas. They were first described from the Pacific (Tracey et al., 1948), and were subsequently found in the North Atlantic (Agassiz, 1895), Brazil (Kempf and Laborel, 1968) and the Caribbean area (Gessner, 1970; Adey and Burke, 1976). Related formations are also known from the Mediterranean (Blanc and Molinier, 1955). They are mainly built by massive or encrusting coralline algae (mostly *Hydrolithon*) Hydrocorals (*Millepora* spp.), Vermetid Gastropods and some corals. Specific

composition varies with surf, slope and nature of substrate (Focke and Gebelein, 1978). Plant and animal populations mingle seaward with those of the reef's outer slope; laterally, the rim may pass to the spur-and-groove structures or to rim-like formations developing directly on rocky shores.

On coral reefs, algal rims often develop by fusion of algal heads. Extreme surf conditions may lead to the development of boilers, terraced pinnacles or blowholes.

Similar morphological structures may be obtained by erosive processes. Bermudian "erosive boilers" generated from the erosion of an emerged stack of soft rock were described (Ginsburg and Schroeder, 1973).

## Relation with sea level

- Some biological components of algal rims (*Dendropoma* vermetids, some *Lithophyllum* and *Hydrolithon*) have a very narrow repartition around MSL; their presence in cores or on elevated shorelines is a precise indicator of past sea levels, with metric or decimetric approximation, and widely used around the world's oceans (Adey, 1986; Pirazzoli et al., 1988; Laborel et al., 1994). Stony corals having a range of – 5 to 10 m tend to be less accurate indicators.

## ANTECEDENT PLATFORMS

Peter J. Davies  
University of Sydney, Sydney, NSW, Australia

### Definition

Antecedent Platforms are the surfaces, usually older reefs which have been exposed to the atmosphere, and which form the foundation for later reef growth.

### Introduction

In the study of coral reefs, the term “antecedent platform” has a special place for three reasons. First, in various guises, it stood as a challenge to Darwin’s championing of subsidence as the principle factor in coral reef growth; second,

it stood against the need for glacial eustasy as a factor in reef growth; and third, as a special case (limestone platforms), and at a later time, it co-defined a new paradigm for the evolution of the foundations of modern reefs. The thinking on antecedent platforms moved therefore from the broad to the specific, from “the alternative” to “center-stage,” albeit coupled with other processes. This contribution traces these views accenting more the later process-related views but placed within the context of the earlier history.

### In the beginning!!

In the middle and early nineteenth century, ideas on reef evolution and growth were dominated by Darwin’s theory that subsidence played a critical role in the evolution of coral reefs from fringing to barrier to atolls (1842) (Figure 1). However, not all agreed on either the occurrence or primacy of subsidence in reef growth. A succession of contributors proposed that reefs accumulated on pre-existing reef platforms (Rein, 1870, 1881), volcanic foundations in the deep sea (Murray, 1880, 1887, 1889), or surfaces of submarine planation (Wharton, 1890, 1897; Gardiner, 1898, 1903, 1904; Agassiz, 1898, 1899). Indeed, Andrews (1900, 1902), for example, proposed that the Great Barrier Reef itself rested on a surface of submarine planation. All attempted to counter the need for subsidence in the evolution of coral reefs, and this continued even after the results of the Funafuti borehole were published, which showed that subsidence at any rate was a crucial factor operating in the evolution of at least that reef (Cullis, 1904), and

**Antecedent Platforms, Figure 1** (a) The Darwinian evolution of coral reefs and (b) Daly's glacial control theory of reef evolution. (Page 10 – Purdy'd 1974 paper.)

subsequent drilling throughout the Pacific has confirmed this (Schlanger, 1963). However, post-Funafuti, the importance of the antecedent platform was as a foil to another idea in understanding the growth of coral reefs, that is, glacial eustasy. In a series of controversial papers, Daly (1910, 1915, 1917, 1919, 1934) proposed that global glaciations had the effect of both lowering sea level and reducing sea surface temperatures, the effects of both substantially impacting the growth of coral reefs. His glacial-control theory, applied initially to atolls, used the glacial lowering of sea level to produce foundations, which were then planated by wave abrasion as the effective process in turning fringing reefs into barrier reefs and then into atolls (Figure 1b). These ideas were extended by Daly himself and by Vaughan (1914, 1919, 1923) to Florida and the Bahamas as well as to the Great Barrier Reef. While some of Daly's evidence has been called into question (e.g., not all atolls have the same depth; his proposed processes and rates of processes are unrealistic, and his proposed time-scales are wrong), there can be little doubt today that glacio-eustatic sea-level fluctuations have profoundly affected how we think about the nature of the platforms on which today's coral reefs have grown. The next step was taken by Kuenen (1933, 1947) coupling glacially produced sea-level fluctuations and subsidence to sub-aerial and marine intertidal erosion to produce partially or completely planated antecedent platforms on which further reef development could occur. And then, in the 1940s, very important papers but in poorly distributed publications, Japanese scientists (Yabe, 1942; Asano, 1942; Tayama, 1952) coupled glacio-eustatic sea-level fall to the nature of the reef foundations for the first time. Thus began the germ of a new set of ideas. The first two papers were by Hoffmeister and Ladd (1944, 1945), which admitted to the reality of sea-level fall but placed the major emphasis on a suitable substrate for subsequent reef growth, that is, any bench or bank situated at a proper depth in the coral seas is a potential reef foundation. In the 1945 paper, however, they reported the results of experiments simulating the effects of rainfall on an exposed limestone surface (a slab of Solenhoffen limestone) as a way to explain the origin of raised atolls. They inferred from their crude experiments that the saucer shape of raised atolls may be related to solution. This was left to MacNeil (1954) who accepted Kuenen's coupling of glacial lowering of sea level and subsidence but invoked sub-aerial erosion to produce the diagnostic annular rim of atolls, which was therefore inherited from a period of earlier sub-aerial erosion (Figure 2). The saucer-shaped basin was therefore the logical consequence of sub-aerial solution acting on exposed Pleistocene atoll foundations.

MacNeil (op.cit) emphasizes the importance of limestone-solution processes involving surface and sub-surface solution and re-deposition and surface case hardening in producing relief features inherited by subsequent reef growth during an ensuing sea-level rise. The accent was clearly placed on inheritance from an exposed eroded surface. Thus, atoll lagoons form on eroded lows, and atoll

rims occupy the surrounding highs. For whatever reasons, MacNeil's ideas were not received with ultra-enthusiasm by the scientific community.

### Antecedence post-1974 – the purdy revolution

In 1974, Purdy (1974) published a seminal paper, inferring cause and effect in linking reef shape to karst-induced antecedent morphology. Drowned atolls reflect drowned karst topography; reef passes originate as drainage breaches in the solution rim; faroes are the karst product of breaching; peripheral islands are exposures of the fossil drainage divide, and spurs and grooves are expressions of lapies. Thus, the karst-induced differences in relief are perpetuated and indeed accelerated by growth, but reef growth per se has little to do with the basic configuration. Paradoxically, a paper proving that the Holocene reef off the north Jamaica coast was a mere mantling of low sea-level Pleistocene terraces (Goreau and Land, 1974) was published alongside Purdy's karst revolutionary paper.

In marked contrast to MacNeil's ideas, the 1974 paper sparked a widespread rethink of the role of antecedence and for a number of reasons: (1) Purdy's ideas applied to barrier reefs as well as atolls and therefore to a much wider scientific community, (2) he discussed processes that were important to the oil industry in developing porosity, once again opening the subject to a science community outside of the academic, (3) he coupled eloquent laboratory experiments to well-illustrated examples of mega-karst morphology from some of the world's notable karst areas, and (4) he used well-illustrated seismic data coupled to drill-hole data across a major barrier reef complex (effectively for the first time), which became well known through the work of Ginsburg and coworkers (Ginsburg and James, 1976; James and Ginsburg, 1976) and Rutzler and Macintyre (1982). Furthermore, when data was lacking he resorted to compellingly acceptable eloquent deductions. Like Hoffmeister and Ladd (1944), Purdy (1974) subjected limestone blocks to acid rain and produced features analogous to both karst and modern reef forms (Figure 2). He emphasized solution rims, enclosed depressions at various scales, conical karst, tower karst, and karst marginal plains as important natural and experimental features, which could have analogs in both atolls and barrier reef systems. He coupled glacially effected sea-level oscillations, subsidence, and sub-aerial erosion to explain their formation (Figure 3). Atoll morphology derives from the development of solution rims on emerged limestone masses; where rainfall is high, breaches in the karst rim give rise to subsequent atoll-passes, while in the interior, a conical karst may develop as antecedent foundations to lagoonal patch reefs; also, collapse dolines may form as a consequence of extensive subterranean dissolution, the forerunner of "blue holes" according to Purdy (1974). Alternately, where rainfall is low, conical depressions (solution dolines) form within the solution rim. The morphology of atolls and barrier reefs is solution determined rather than growth predicated (Purdy and Winterer, 2001) (Figure 4).

**Antecedent Platforms, Figure 2** MacNeil's (1954) diagram showing the development of atolls and faroes from sub-aerial erosion forms. (See Hopley (1982, p. 19).)

General support for Purdy's ideas comes from the saucer shapes of many modern reefs, the many enclosed depressions within them and the fact that many modern reefs are underlain by earlier reefs. In addition, there can be little doubt that some tropical karst landforms do have similar morphologies, as evidenced particularly in the atolls at Kita Daito Jima, at Mare and Lifou in the Loyalty Isles, and at Makatea in the Tuamotus (Bourouilh 1977). More recently, Purdy and Winterer (2001) show convincingly that atoll-lagoon depths (and therefore gross atoll morphology) are directly related to the amount of rainfall and the catchment size, indicating solution as a dominant process, but one which occurs accumulatively over many solution periods. In spite of this wealth of support however, it is Purdy's description and deductions regarding the evolution of the Belize Barrier Reef (Purdy, 1974) that add major weight to his hypothesis. Of particular importance are the identification of joint-related dolines in the northern region, the development of onshore karst dipping eastwards below the present shelf, the relations of the central province rhomboid shoals to underlying pre-Holocene

morphologies, and, most importantly, the southward narrowing of the Belize Barrier along a proposed karst-marginal plain increasingly effected by the proximity of the silica-dominated Maya mountains and increased rainfall. Underlying this detail, Purdy et al. (2003) also document an essential structural control on the distribution of platforms on which the carbonates have been disposed. In short, Purdy and his coworkers have covered the field in elucidating the geological and climatologic factors that have combined to produce the Belize Barrier Reef system, but emphasizing the importance of low stand sub-aerial erosion in sculpting the gross architecture.

In spite of the above, however, not all have been convinced of the role of karstic antecedence. From a theoretical viewpoint, young reef limestones are not thought to be mechanically suited for karst development (Jennings, 1971) while Ollier (1975) demonstrated conclusively that in a high rainfall region like the Trobriand archipelago off New Guinea, the raised Quaternary reefs have undergone very little surface karst erosion. Further, on the exposed raised reefs of Barbados, the extent of karstic

**Antecedent Platforms, Figure 3** The effects of rainfall on blocks simulated by dripping acid onto limestone surfaces (a) Rainfall (acid) is sufficient to produce a single acid meniscus over limestone surface; this produces a peripheral rim; (b) Rainfall (acid) insufficient to cover top surface so meniscus breaks up into a series of smaller menisci; the result is a rim bounded block in which the central depression has been residual solution prominences; and (c) Rainfall (acid) is more than sufficient and runs down the blocks: result is that the block just gets smaller.

solution is directly related to the age of the limestones, that is, depressions in the 120 k reef are only 1 m deep, while in the >480 k reef, they are 12 m deep. Clearly, any karstic solution is cumulative, and Purdy (1974) recognized this, repeating again in 2001 (Purdy and Winterer) that in terms of gross morphology, the dissolution process is cumulative. Most now agree on this. However, an important question is still the extent to which the previous reef (usually the 125,000 years old reef) has affected the growth pattern of the modern reef, and this will depend on the amount and degree of erosion of the previous reef. Purdy himself was unsure about this, noting the work by Land et al. (1967) again on Bermuda and concluding that a net reduction of the exposed surface by up to about 4.5 m was likely. However, as a general conclusion, this is at odds with the facts, that is, beneath Belize and the Great Barrier Reef, the depth to the 125 k antecedent surface can be anything from –10 to –25 m below present sea level. Assuming the 125 k reef grew to sea level, then the present depth indicates 10–25 m of erosion plus subsidence in the intervening period, clearly at odds with the Bermuda conclusions. It is however in agreement with conclusions in Purdy and Winterer (2001) for gross surface erosion rates on Pacific atolls. In addition, if one uses the vertical erosion rates for coral and coralline algae published by Trudgill (1976) for Aldabra, then vertical erosion of the coral flat and algal flats in the Great Barrier Reef and exposure for around 95,000 years out of the last 125,000 years, then the surface of the 129 k reef is eroded only about 10 m. Coupled with estimated subsidence in the same time frame (5 m or so), the pre-Holocene surface would be at –10 m prior to the growth of the Holocene reef. This is in fact the depth that it is at on a number of reefs in the Great Barrier Reef (Davies and Hopley, 1983). While this solution/erosion is enough

to produce small-scale features, some of which may be inherited by the modern reef, it is clearly insufficient to have produced the large-scale features on the scale of barrier reef systems or reef tracts. Such features, Purdy says are the result of repetitive cumulative karstification. In the Great Barrier Reef, the idea of a karst marginal plain is no longer in favor (Hopley et al., 2007).

Since the seminal 1974 paper, Purdy has become more sure of his ground although even in 1974, he showed the direction in which his thoughts were moving – “Thus the major premise of the subsidence theory (Darwin’s) has been confirmed. It would be dangerous, however, to assume that this subsidence necessarily proves the genetic succession of reef types advocated by Darwin” (Purdy, 1974, p. 10). Further, quoting Vaughan’s warning in 1919 (p. 325) – “although the theoretical possibility of the conversion of a fringing reef into a barrier reef and a barrier reef into an atoll may not be denied, no instance of such a conversion has yet been discovered,” Purdy makes it clear that the evolution of reef types proposed by Darwin is open to question. In 2006, he states that “there are no examples of the subsidence-predicted transition of fringing reefs to barrier reefs to atolls. Moreover, the common occurrence of fringing reefs within barrier reefs negates subsidence as a causal factor in their presumed progressive evolutionary development” (Purdy and Winterer, 2006, p. 143). Instead, Purdy advocates a solution morphology template accentuated by reef construction particularly for barrier reefs.

### Growth antecedence

This was first proposed by Bloom (1974) and states quite simply that original reef facies exerts a fundamental control

**Antecedent Platforms, Figure 4** Diagrammatic evolution of atolls and barrier reefs according to antecedent karst theory. (Purdy Page 71)

on antecedence inheritance. The highly permeable reef framework and coarse rubble facies would be more resistant to solution erosion as they would be the highest above the water table and rainwater would pass rapidly through. Uncemented lagoonal sand and mud facies however would more likely be susceptible to solution. Thus, weathering across the reef would emphasize the constructional relief differences between reef and lagoon floor, such that re-submergence would situate reef facies above reef facies and lagoon facies above lagoon facies. This is not at odds with Purdy's ideas (above) as was proposed by some, but is a special case of it, as the karst is occurring on reef limestones (whereas Purdy's experiments and actual examples showed karst developing on most limestones).

Proof for these ideas requires detailed analysis of lithology immediately above and below the unconformity separating two periods of reef growth, and has been shown particularly in Belize but also in the reefs of the southern Great Barrier Reef where detailed mapping of facies distribution has occurred. At Ambergris Cay, at the northern end of the Belize Barrier Reef, Tebbutt (1975) showed that the exposed Pleistocene facies is a reef crest limestone with the same assemblage of corals as the modern reef crest.

A priori, however this shows reef growing on reef. In the southern Great Barrier Reef, a similar relation occurs. In particular, the algal rim some 50–100 m wide, which acts to protect the reef from wave destruction during the high stand, also offers protection during the low stand against sub-aerial weathering. It is dense, hard, and has a much reduced porosity compared with the adjacent open framework coral dominated facies in front and behind. The reef flat coral facies (leewards of the algal flat) which is 200–300 m wide, has a high porosity with a likely low retention time for percolating water during sub-aerial conditions. The sand flat facies between the coral flat and the lagoon has 40% porosity and is unlithified; it forms a boundary of around  $30^\circ$  with the lagoon and would be subject to substantial erosion and re-deposition down slope during periods of emergence. This unlithified edge would therefore retrograde backwards towards the inner edge of the coral flat. The reef front facies, in spite of being well lithified is also highly porous, and would be prone to cavern development and collapse under the influence of gravitational instability. Erosion would therefore be greatest in two areas, the fore reef (front, spurs, and grooves) and also along the edge of lagoon and sand flat. The effect of these specific areas of

erosion would be that the algal-dominated reef flat and the coral flat will stand up as a high rim. During the ensuing submergence, a new reef will first occupy the high ground on the previous reef and eventually grow at a still stand sea level with bio and sediment facies distribution similarly distributed to the reef below. Note that some modern patch reefs grow on top of earlier patch reefs, indicating a quite specific control on re-growth; that is, the reef is not growing on conical karst but on earlier patch reefs. Thus, in the Pleistocene, dominated by oscillating sea levels, a stacked succession of reefs will form through the combined effects of sea-level change, subsidence, and sub-aerial erosion (see Davies et al., 1988). In the case of the southern Great Barrier Reef, the periods of reef growth have been short (<10,000 years) compared with the periods of sub-aerial erosion of the previous reef (around 100,000 years). The driving force for the amount of reef stacking is clearly the frequency and magnitude of sea-level change.

The likelihood that this model also applies to Pacific atolls is high because they have a similar shape and facies distribution to that described above for the reefs of the southern Great Barrier Reef. The effects of a sea-level fall on an atoll would be to particularly expose the highly porous reef front, much of which would be removed and re-deposited down slope. The algal flat however would resist rapid erosion and form a protective cap above the catch-up coral facies below. The lagoon would remain a depositional low, although depending on the magnitude of the sea-level fall, it may contain a low stand lake or a saline pool connected to the ocean through the body of the exposed reef. Subsequent reef growth would eventually stack above the previous reef. Expansion of the facies laterally would be impossible on the outside of the reef because of the steep slopes. An example of such growth is Mururoa (Buigues, 1985; Guilcher, 1988), in that most atolls have similar characteristics to Mururoa (reef top biofacies distribution and steep external slopes inhibiting facies migration on the front), and most would also react to sea-level oscillations in the same way. Thus, in the Pleistocene at any rate, the high stand growth of platform reefs and oceanic atolls reflect two factors: (1) a high stand facies control of low stand produced inheritance features and (2) growth controlled largely by the direction and amount of energy input (See *Great Barrier Reef: Origin, Evolution, and Modern Development*; also Davies, 1983; Davies and Hopley, 1983). It is important to note however that in this model rapid sea-level oscillations are important. Change the oscillation pattern and a different effect will occur. For example, increasing the length of the low stand period may obliterate the effects of facies control. Increasing the lengths of the high stand will serve only to produce flat topped reefs.

### Non-karst antecedence

Reef growth has been shown to occur on antecedent surfaces that are not limestones. In the Pacific, Murray's original ideas (1880, 1887, 1889) that volcanics form a surface off which reefs have grown holds true. Perhaps less

obvious, however, are Choi and Holmes (1982) and Choi and Ginsburg (1982) work that show that late Pleistocene and Holocene reefs are growing on siliciclastic sediments, which have an alluvial and delta-like morphology. The residual relief of these coastal plain sediments localized initial coral growth; favored sites for such growth were elevations such as levees and bars of remnant channels and deltaic lobes. Thus, the unique rhomboid and long sinuous lagoon reefs are derived from the early Pleistocene river morphology and not from a fault dominated karst morphology as suggested by Purdy (1974).

### Conclusions

A consideration of reefal platforms began with Darwin's startling hypothesis that subsidence was paramount and drove fringing reefs to become barrier Reefs and ultimately atolls. In opposition the role of substrate was raised early, and then in conjunction with glacial control and sub-aerial erosion, it has risen to a position of general acceptance as a dominating process in the evolution of barrier reefs and atolls. Such antecedence is generally limestone based, and in some cases that antecedence has been shown to be facies controlled. However, antecedence has also been shown to occur off siliclastic foundations. There can be little doubt, however, that much antecedence is produced by low sea-level erosion.

Atolls are underlain by subsiding volcanic basements with steep peripheral slopes and surrounded by deep water. The limestones comprising the atoll platform can be tropical or temperate depending on their latitudinal position. During periods of oscillating sea level, the platform surface may be exposed, and karstic erosion set in, the effects of which will be the development of a raised rim which may or may not be breached, a central depression and conical karst features within the lagoon. Subsequent sea-level rise will allow growth preferentially such that it mimics the positive underlying topography, thus inheriting the eroded shapes.

In the formation of Barrier Reefs, a critical feature is the formation of a "karst marginal plain" – effectively an exposed shelf, carbonate dominated in the outer part and siliceous or non-carbonate in the inner part (effectively most shelves) – exposed as a consequence of a fall in sea level. Consequent sub-aerial erosion would occur to a maximum at the boundary of carbonate/non-carbonate rocks effecting the formation of tower-karst. Elsewhere in the carbonate-dominated area, a raised rim would form proximal to the outer steep slope (a la atolls) and conical-karst would form over the outer carbonate shelf (Figure 2). Following the subsequent rise in sea level, platform reefs would develop over the tower-karst and a barrier reef would develop over the outer shelf rim.

## ARAGONITE

Sue J. McLaren  
 University of Leicester, Leicester, UK

### Definition

Aragonite is a mineral comprising calcium carbonate ( $\text{CaCO}_3$ ), it is polymorphous to *calcite*, meaning that they both contain the same main elements but have different crystal structures. Aragonite forms orthorhombic crystals, whereas *calcite* is trigonal. Aragonite is characterized not only by pseudo-hexagonal crystals but also acicular habits, often in the form of radiating groups of needles, which are also common. Aragonite has an imperfect to poor cleavage, a subconchoidal fracture, and a hardness on Moh's scale of 3.5–4. Aragonite tends to be colorless or white, and most are relatively pure, with strontium and lead, acting as the most common substitutions for calcium. Aragonite is highly soluble in cold dilute hydrochloric acid, resulting in significant effervescence. Feigl's solution stains aragonite black, whereas *calcite* remains unaffected.

Aragonite most commonly precipitates in seawater and so is found in marine sediments and forms the shells of some marine organisms. The skeleton of scleractinian corals are composite organo-minerals comprising organic matrices and inorganic aragonite crystallites. Aragonite is a meta-stable form of calcium carbonate and over time undergoes transformation to the more stable *calcite* polymorph. Aragonite is more soluble than *calcite* in the meteoric environment and dissolution results in the partial or total loss of the aragonite clasts, matrix and cements, often leaving molds. These molds along with primary pores may subsequently be infilled by allochthonous *calcite* cement.

Alternatively, neomorphism may occur by a concomitant dissolution of aragonite and reprecipitation of autochthonous low-magnesian *calcite* cement (e.g., Rabier et al., 2008). On land, aragonite can be found in dryland environments associated with evaporite minerals such as halite and gypsum. Aragonite also forms speleothems in caves, tufa, and travertine as well as sinter in hot springs.

## ATOLL ISLANDS (MOTU)

Roger McLean  
 University of New South Wales, Canberra, ACT, Australia

### Synonyms

Cays; Gravel islands; Islets; Keys; Rubble islands; Shingle islands

### Definition

Atoll islands are morphologically coherent wave-built accumulations of bioclastic sediment, located on atoll rims or on patch reefs within atoll lagoons, and emergent at all stages of the tide. They can be of any size and shape and are characterized by low elevation (typically 2–4 m above MSL), shallow alkaline soils, absence of surface water, and a limited terrestrial biota. Atoll islands are composed of skeletal sands and/or coral rubble sourced from the adjacent reef or lagoon. On sea-level atolls, islands are geologically very young having accumulated during the mid-late Holocene. In spite of this short time frame, some unconsolidated island sediments have become indurated to form phosphate rock, cay sandstone, beach rock, and beach conglomerate, which offer some stability to atoll islands. *Motu* (n) is the word for any island or islet in many Polynesian languages, including Maori, Tuvaluan, and Paumotu, although the word has been given more specific meanings in coral reef geomorphology.

### Number, dimensions, and location of atoll islands

*Atolls* are annular reefs around a central lagoon. The reef rim may be continuous, or broken by a few channels as is common in the central Pacific, or have many shallow passes or *hoa* as in French Polynesia, or deep passages as in the *Maldives*. Rarely are rim reefs completely

occupied by islands, and equally rarely are no islands present. In the Maldives there are about 1,200 islands in its 21 administrative atolls, while in the Tuamotus most of the 75 atolls have over 20 islets each, with about 280 islets on the atoll of Raroia. Wiens (1962) has shown that the number of islands on atolls and the area they occupy decrease westward across the Pacific from the Tuamotu archipelago to the Caroline Islands.

Atoll islands are small and often cover only a small fraction of the available reef space. For instance, on the five main atolls in Tuvalu (Nanumea, Nui, Nukufetau, Funafuti, and Nukulaelae), there are 113 islands that occupy just 1–18% of the possible reef platforms. Here the average island size is 13 ha, but the majority are tiny with fifty-one <1 ha, another twenty-seven <5 ha, and only four >100 ha, the largest being 220 ha. Similarly, in the Maldives on South Malhosmadulu atoll there are 53 islands with a mean size of 10 ha and range from <1 to 46 ha. On this atoll the average proportion of reef platform occupied by islands is 28%, with a range from <1 to 71%. In both Tuvalu and the Maldives frequency distributions of island size and proportion of available reef occupied by islands are strongly skewed toward the lower values, a common situation throughout the atoll world.

Within atolls, islands are unevenly distributed around the reef rim to windward and leeward, particularly in the Pacific where the trade winds dominate. In many cases islands are concentrated along the eastern (windward) reef, with a tendency toward the southeast sector in the Marshall Islands and the northeast in the Tuamotus. Frequently, these windward islands are narrow linear features which tend to be closer to the lagoon shore than to the ocean reef edge. Along the western side (leeward) of Pacific atolls the reef is often discontinuous with fewer and more compact islands. Islands are rare within lagoons of Pacific atolls. In the Indian Ocean the distribution of reefs and islands is different. In the Laccadive–Maldivian archipelago, atoll rims are typically more open, and islands occupy reefs both around the eastern and western margins as well as within the central lagoons. This more regular distribution of islands is primarily a consequence of the seasonal reversal in monsoonal conditions.

## Motu

In coral reef literature, the Polynesian word *motu* has a more restricted meaning than simply “island” or “islet,” although usage has not been consistent. In Stoddart and Steers’ (1977) classification, reef islands with a high seaward shingle ridge or ridges and a lower sand area to leeward are called *motu*, to distinguish them from pure sand cays or pure shingle cays. Such *motu* are typically associated with high-energy environments on the windward rim of atolls. Other authors equate *motu* exclusively with coarse-grained sediments, coral gravel, and cobbles, to separate them from simple sand cays. On the other hand, Richmond (1993) uses the more general meaning of *motu* to mean any atoll islet or island. Note that in New Zealand

Maori language *motu* is not limited to an islet or island, but can also refer to any land, clump of trees, ship, or anything else that is separated or isolated.

## Classification of atoll islands

There have been several classifications of reef islands (see *Coral Cay Classification and Evolution*) and these can be equally applied to islands on atolls. However, there are two well-known classifications specifically for atolls. The first by MacNeil (1972) who classified atoll islets “according to the way they are formed” noting that most atoll islands in the northern Marshall Islands are accumulations of sediments around obstructions of rock, the most common obstructions being platforms of raised reef, storm rubble tracts, and beach rock. Hence, three main types are distinguished:

- Type 1 islets are formed on platforms or eroded remnants of raised reef
- Type 2 islets are formed on rubble tracts of storm-cast debris
- Type 3 islets are formed from consolidated sand bars or beach rock

Special islets, including combinations of the above, were recognized as the fourth type.

More recently, Richmond (1993) distinguished four types of atoll islets based on morphology, sediment and rock characteristics, and position on reef rim from observations in western Kiribati, Tuvalu, and the Cook Islands:

- Type 1 islets are analogous to sand cays and occur primarily adjacent to reef passages on the leeward rim or atop lagoon patch reefs
- Type 2 islets are typically U-to-boomerang shaped and develop on high energy complex bends of the atoll rim
- Type 3 islets are narrow, elongated gently curved to sinuous in plan shape, and are composed primarily of several parallel ridges which are often separated by a central depression.
- Type 4 islets are complex landforms developed around cemented rubble and reef flat deposits and exhibit a wide variety of shapes.

This last class of islets corresponds closely to the first two islet types of MacNeil’s classification above.

In addition to these scientific classifications, most atoll states and communities have local words or terms to describe the range of typical islands in their territories. Thus, in the Maldives, island classification is based on the presence or absence of vegetation, typical sediments, and relative size. Large vegetated sand islands are known as *raa* and smaller ones as *fushi*. *Huraa* are vegetated shingle or rubble islands. Unvegetated islands include *finolhus* for sand cay/banks and *huraagandu* or *huraalette* for shingle cay/banks. Throughout much of Polynesia, prefixes or suffixes provide further descriptions of atoll *motu* such as *Motu-iti* = small island, *Motu-one* = sand island, *Motu-loa* = long island, and *Tua-motus* = islands on the ocean’s back.

## Geomorphic features of atoll islands

Regardless of island size or shape, and despite their low absolute elevation, atoll islands possess subtle but recognizable variations in surface topography which reflect both geomorphic processes and sediment types. Three natural landform units can often be distinguished: a high-gravel ridge or ridges on the ocean or windward side; a low-sand flat ridge or ridges on the lagoon or leeward side; and a central depression or flat between the two. This asymmetric topographic form is also present on islands comprising a single sediment type, either sand or gravel. However, on islands located in environments where there is no clear windward or leeward side, islands are commonly basin shaped with a high peripheral ridge of roughly equal elevation encircling the whole island. Classic examples of this topographic form occur on the circular patch reefs within lagoons of Maldivian atolls.

On most atoll islands the highest natural elevation is the wave-emplaced ocean side or peripheral beach ridge, which commonly reaches 3–4 m above MSL. On some islands, however, the beach ridge is topped by a dune of fine wind-blown sand, although the presence of sand dunes is not a usual feature on most atoll islands. Where dunes do occur they reach higher elevations than wave-formed ridges, on *Cocos (Keeling) Islands*, up to 5.5 m above MSL on Home Island, 7 m on West Island, and 11 m on South Island (based on surveys reported by Woodroffe and McLean (1994)).

Excluding sand dunes, the highest elevation on atoll islands, and often the greatest and most complex relative relief, results from human activity rather than natural processes. From French Polynesia in the Pacific to the Laccadive–Maldivian archipelago in the Indian Ocean, crop cultivation, especially for taro and banana, is universally carried out in flat-floored depressions or pits excavated down to the island water table. Spoil dug from the pit is dumped around the pit edge building a spoil bank above the level of the surrounding land. The resulting topography is frequently chaotic, especially where groups of pits and banks occur in close proximity to one another.

## Sediments, soils, and groundwater

Atoll islands are made up of calcareous sediments, primarily the skeletal remains of organisms living on the adjacent reef or in the lagoon. Invariably, the coarsest materials comprise whole or broken clasts of coral, typically of sizes from a few centimeters to a few decimeters. In contrast to this single taxa dominance in the gravel and rubble fraction, sand-sized sediments may include small coral fragments, but more commonly comprise a mix of coralline algae, mollusks, foraminifera, and *Halimeda*. Both the calcareous and textural characteristics of the sediments have a major influence on soil properties. Not surprisingly, atoll soils tend to be light colored, shallow, alkaline and coarse textured with no clay. Fertility is highly dependent on the organic matter

content primarily from vegetation and leaf litter, and moisture retention is generally low. Atoll soils are also excessively well drained; water from rainfall quickly percolates to the water table. Fresh water generally tops the groundwater lens within atoll islands, beneath which is the denser saline water originating from the surrounding ocean and lagoon. Traditionally, the fresh water lens has been used as the primary source of potable water by atoll communities.

## Processes of formation and change on atoll islands

Islands accumulate on atoll reefs where sediment is available and where wave processes are focused, often as a result of wave refraction around the reef. Frequently, island shape mimics that of the reef, several examples from Tuvalu being cited by Richmond (1993). Whether or not islands will form on atoll reefs is also dependent on the strength of wave energy. A west to east traverse across South Maalhosmadulu atoll in the Maldives shows that continual high wave energy on the western reef rim sweeps sediment right across the reef platform and islands only occur on the broadest reef flats. In contrast, on the eastern atoll rim where wave energy levels are lower, islands occur on most of the available reef platforms. The more equal and lowest magnitude wave energy of the central atoll ensures mobile sediments are trapped on reef tops, the resulting islands occupying a large proportion of the available reef surface (Kench et al., 2006).

Catastrophic storms have also been regarded as a primary mechanism in the initiation of atoll islands and especially *motu* as recognized in the classifications of MacNeil (1972) and Richmond (1993) outlined earlier. The hurricane/typhoon hypothesis of island formation has a long history with strong support from some of the greatest late nineteenth- to early twentieth century reef scientists based on observations particularly in the *Cocos (Keeling) Islands* and *Funafuti Atoll*. Modern analogues of the delivery of large masses of coral debris to reef surfaces by tropical storms abound; the massive rubble banks formed during Typhoon *Ophelia* at Jaluit atoll in January 1958 and Hurricane *Bebe* at Funafuti in October 1972 provide two excellent examples. Indeed, as MacNeil (1972) and many others have noted, without storms most islets would not be built, and because of storms some islets become larger, while others are reduced or disappear. One implication of this is that sediment delivery is episodic, a point stressed by Wood-Jones (1912: 261) who based on his experience on Cocos (Keeling) proposed a “law of atoll growth” stating that “the processes of formation take place in fits and starts.”

A more critical assessment of the role of episodic storms and fair weather periods was developed by Bayliss-Smith (1988) who modeled the difference in response between gravel *motu* and sand cays on Ontong Java atoll, Solomon Islands. Storms result in a net input of coarse rubble on *motu*, but they cause shore erosion

on sand cays. During subsequent fair weather, storm rubble is redistributed on *motu*, while sand cays recover from the erosional episode and buildup between storms. Bayliss-Smith's model has proved a robust one and has been modified and expanded by several other researchers.

In contrast to the well-documented impacts of tropical storms on atoll island construction and destruction, the impact of tsunami is more ambiguous, even though atoll islands throughout the Indo-Pacific region must have been subject to multiple tsunami during their geological histories. Few investigations of the impact of tsunami on atoll islands have been made, the Sumatran tsunami of December 26, 2004 being a notable exception with several studies of its effects on the Maldives. While the tsunami had tragic consequences for many inhabited islands in the Maldives, pre- and post-tsunami geomorphic surveys on a number of uninhabited islands showed both erosional and depositional changes, little major damage, and a net long-term effect favoring island accretion rather than reduction (Kench et al., 2008).

### Stabilization processes

Once formed, atoll island deposits can be stabilized by a number of different processes including colonization by terrestrial and littoral vegetation and lithification of island and beach sediments. Vegetation, through root binding and the accumulation of humus, stabilizes land surfaces and enables soil formation to proceed, while along island margins root masses of coconut palms, pandanus, and broadleaf trees often form conspicuous "phyto-revetments." Island shores can also be protected by a fringe of intertidal mangroves or *Pemphis* that serve to slow down particle movement and entrap sediment.

Lithification of unconsolidated deposits can also take place, both within islands and around their margins. Examples of the former include the formation of phosphate rock and cay sandstone (*Phosphatic Cay Sandstone*), while beach rock and beach conglomerate (*Conglomerates*) or breccia are common littoral rocks, which give an island some resistance. Both form natural sea walls and groynes and serve to protect an island from erosion. They can also form a locus for island accretion, and are included in MacNeil's classification of atoll islets (Types 1 and 3) and that of Richmond (Type 4).

### Origin and development of atoll islands

Islands on sea-level atolls are geologically young, having developed only in the last few millennia (mid-late Holocene). Obviously, island accretion postdates the surfaces on which the islands are built, be that surface conglomerate platform, solid reef flat, or lagoonal sediment. Many researchers have suggested that the formation of islands on atolls was triggered by a slight fall in sea level from a mid-Holocene high stand. Such an interpretation has been advocated for a large number of atolls extending from the southernmost atoll in French Polynesia (Temoe)

through the Tuamotu archipelago and Cook Islands in the Pacific to Cocos (Keeling) Islands in the eastern Indian Ocean, where the majority of islands are perched on a conglomerate platform or emergent reef flat (Woodroffe and McLean, 1994). On the other hand, there is evidence to indicate that some atoll islands accumulated earlier, when sea level was rising rather than falling, as demonstrated by Kench et al. (2005) for islands in South Maalhosmadulu atoll in the central Maldives.

It is evident from this analysis that there are several ways in which atoll islands can form, including through storm wave action, and that they have formed at different times over the last few millennia (McLean and Hosking, 1991). Moreover, some islands may have developed episodically and others incrementally. Woodroffe (2000) has proposed a number of different scenarios to illustrate chrono-sequences of island accumulation such as accretion away from a central core, progradation in a lagoonward or oceanward direction, or through sediment rollover or overwash. More recently, quantitative models using morphodynamic principles have been used to test field-based models and to suggest that there is a growth-limiting size to atoll islets (Barry et al., 2008).

### Future status of atoll islands

Due to their small size, low elevation, and reliance on locally generated reefal sediments, atoll islands are considered particularly vulnerable to the effects of climate change and especially sea-level rise. The principal impacts from sea-level rise are expected to include: shoreline erosion, inundation and flooding, and saline intrusion, the consequences of which may be to reduce island size, waterlog low-lying areas, and contaminate fresh groundwater supplies. Given these potential impacts, it is surprising so little substantive research has been done on these issues in the atoll world. However, the research that has been done suggests that atoll islands may be much less vulnerable than portrayed in the media or by atoll governments. Geomorphic studies such as the recent comprehensive analysis by Woodroffe (2008) indicates that atoll islands exhibit a degree of physical resilience, that sea-level rise is not the only climate change issue of relevance to atoll islands, and that the key message is that islands will differ in their susceptibility to sea-level rise. Woodroffe's conclusion reiterates an earlier comment by Richmond (1993: 1193) that even within an atoll "different islet types could respond differently to such climate changes as sea-level rise and increased (or decreased) storminess."

Finally, it is interesting to recall that nearly 50 years ago Wiens (1962: 135) wrote about the fate of atoll land with rising sea levels as follows: "In the next 5,000–6,000 years it is possible that periods of rising sea levels may inundate most present land on atolls and possibly destroy most present reef islets." Perhaps Wiens' time scale is an order of magnitude or two out as we may already be in one of those "periods of rising sea levels."

## ATOLLS

Colin D. Woodroffe, Naomi Biribo

University of Wollongong, Wollongong, NSW, Australia

## Definition

Atolls are annular mid-ocean reefs; the reef rim supports isolated, or near-continuous, reef islands composed of un lithified or poorly consolidated sand or gravel, and encloses a central lagoon.

## Introduction

The term “atoll” is derived from a Maldivian (divehi) word, *atolu*. Atolls are ring-shaped reefs that occur in mid-ocean, often in linear island chains or archipelagoes. The most extensive groups of atolls occur in the Pacific Ocean but there are also numerous atolls in the central Indian Ocean (Figure 1). The reef platforms that form atolls are generally characterized by reefs that reach sea level, especially on the windward margin of the reef platform, although there is considerable variation in the extent to which the reef crest is continuous around the entire perimeter of the central lagoon. There are several hundred atolls which occur across a wide range of climatic and oceanographic conditions (Bryan, 1953), and show a wide variety of shapes (Stoddart, 1965; Shimazaki et al., 2006).

Although there is consensus that many mid ocean reefs are atolls, it is more difficult to settle on an unambiguous definition of what constitutes an atoll. The scientific study of atolls owes a considerable debt to Charles Darwin, first because of his insight into reef development and the evolution of atolls, but also because he produced a map of the distribution of known atolls, as well as other reef types, which focused on the geological factors related to where atolls have formed.

Definitions of an atoll vary, but emphasize several factors in common. Shepard considered an atoll: “an oval-shaped coral reef surrounding a lagoon in which there are no islands other than slightly emerged reefs or small sand cays” (Shepard, 1948, p. 251). Wiens, in his book on atolls, suggested that atoll shape is too irregular to be captured by this definition, and believed that the definition by Kuenen is preferable: “all more or less continuous reefs surrounding a distinctly deeper lagoon with or without lagoon reefs... which rise from a sea bottom which is too deep for the growth of coral reefs” (Newell and Rigby, 1957, p. 21, following Kuenen). Wiens proposed his own definition: “an atoll is a more or less continuous emerged or slightly submerged calcareous reef surrounding a distinctly deeper lagoon or several such lagoons without emerged volcanic islands, which stand apart from other islands, and whose upper seaward slopes rise steeper than the repose angle of loose sediments from a generally volcanic foundation too deep for the growth of reef corals” (Wiens, 1962, p. 8).

**Atolls, Figure 1** The global distribution of atolls, map produced courtesy of Reefbase (<http://www.reefbase.org>).

Although most atolls have a lagoon, sheltered from open ocean swell by the peripheral reef, there are also numerous small platforms, which instead of a lagoon, may be dominated by a single island in the middle of these smaller platforms. These are generally called table reefs, following Tayama (1952), and on those where an extensive reef-top island has formed there is often a swampy central depression.

In the Pacific Ocean there are more than 80 atolls in French Polynesia, most in the Tuamotu Archipelago (Agassiz, 1903a; Guilcher, 1988). There is a prominent chain of atolls that used to be known as the Gilbert and Ellice islands; the Ellice Islands now form Tuvalu. The Gilbert chain is now part of Kiribati; it comprises a sequence of atolls (Richmond, 1993), and there are additional atolls in the Phoenix and Line groups (Keating, 1992). Atolls are extensive through the Marshall and Caroline Islands, with several other atolls in the Federated States of Micronesia. Many of the Cook Islands are atolls, and three atolls comprise Tokelau. The northernmost atoll is Kure in the northwestern Hawaiian Islands at 28°45'N (Riegl and Dodge, 2008). The southernmost is Ducie Island in the Pitcairn Islands group (24°40'S), although Elizabeth Reef in the Tasman Sea at 29°58'S is further south, but may not be a true atoll as it might have formed over a truncated volcanic basement (Woodroffe et al., 2004).

In the Indian Ocean, the Maldives comprise a double linear chain of atolls (Figure 2). The Maldives were the subject of detailed descriptive accounts by Alexander Agassiz (1903b) and Stanley Gardiner (1903). This chain extends through the Laccadives (Lakshadweep) Islands to the north, as a single chain. Minicoy, which was described in detail by Gardiner in his descriptions of Maldivian reefs (Gardiner, 1903, 1931), is the southernmost of this group which has received much less study (Siddique, 1980). A more variable group of reefs comprises the Chagos

archipelago to the south (Sheppard and Seward, 1999). There are outlying atolls in the Seychelles and southwest Indian Ocean (Stoddart, 1973a), and the Cocos (Keeling) Islands in the eastern Indian Ocean (Woodroffe and Berry, 1994).

Atolls are relatively rare in the Caribbean; Stoddart (1965) suggested that there were 27, but Milliman (1973) considered only 10 to be atolls. Reefs such as Hogsty Reef in the Bahamas and Roncador Bank off the east coast of Nicaragua have been described as atolls; however, they clearly differ in origin and morphology from Indo-Pacific atolls. Three atolls have been described just east of the Belize barrier reef (Stoddart, 1962; Gischler, 1994).

The largest atoll is Suvadiva (Huvadhu) in the Maldives with an area of 2,800 km<sup>2</sup>; the largest land area is on Christmas Island (Kiritimati) in Kiribati with an area of 321 km<sup>2</sup>. Raroia in the Tuamotu has a lagoon area of 171 km<sup>2</sup>. Kwajalein measures 120 by 32 km, Rangiroa 79 by 34 km, and Tijger, south of Sulawesi, 72 by 36 km.

There are several types of atoll. Atolls can be classified into ocean atolls and shelf atolls (Ladd, 1977). The ring-shaped reefs in open ocean, which we now realize to be in a mid-plate setting, were mapped in detail by Darwin and are unambiguously atolls. However, there are several other groups of islands that contain reefs that have been classified as atolls. For example, the numerous reefs of the Indonesia archipelago contain some of the most diverse of island groups (Kuenen, 1933). At least 55 are considered atolls by Tomascik et al. (1997). There are also a series of reefs in the South China Sea, where three types of atolls have been recognized: ocean atolls, shelf atolls, and slope atolls (Wang, 1998). Whereas the South China Sea islands include true oceanic atolls, such as Scarborough Reef (Huangyan Dao, Wang et al., 1990), those further north are shelf atolls and there are also a series of 70 continental slope atolls in intermediate water depth.

**Atolls, Figure 2** The Maldivian archipelago which for much of its length comprises a double chain of atolls, but reduces to single reef platforms to the south.

Although shelf atolls are also found elsewhere, such as off the northern coast of Australia (e.g., Rowley Shoals and Seringapatam Atoll on Timor Shelf, see *Western Australian Reefs*), slope atolls have rarely been described.

A further variant of an atoll is a reef called an almost atoll. This term has been used differently by different authors; sometimes it has been used to refer to a rapidly subsiding volcanic island that did not form an atoll. However, it is generally taken, in the sense used by Davis (1928), to refer to a residual volcanic island that is surrounded by an annular reef, and which will be an atoll when the remaining volcanic rock has subsided below the level of the sea. Chuuk (Truk) is a classic example, but Aitutaki is an almost atoll in the southern Cook Islands, which has been described in detail by Stoddart (1975).

There has also been recognition of a class of bank atolls, sometimes referred to as submerged atolls, that includes banks on which reef growth does not reach sea level. There are examples in Palau and the Caroline Islands, and Saya de Malha in the Indian Ocean. A further category comprises atolls that are “raised” or emergent, in which older limestones are exposed. Reef limestones of last interglacial age have been found to underlie the rim of atolls at depths of 10–20 m (described below), and on several atolls these outcrop at the surface, or as in the case of Aldabra and Henderson Island, are the dominant subaerial limestone (Braithwaite et al., 1973; Pandolfi, 2008). Elevated atolls include Maré, Lifou and Ouvea in Vanuatu, Makatea in French Polynesia, Nauru, and Niue. Older limestones record successive periods of accretion, and many of these limestones are dolomitized or contain phosphate deposits that have often been mined. Mataiva in the Tuamotu Archipelago also has exposures of Tertiary limestone.

### Surface morphology

The general topography and geomorphology of atolls was outlined in a book by Wiens, entitled *Atoll Environment and Ecology*, based on detailed studies sponsored by the Pacific Science Board and focused on the Marshall Islands, as well as selected other Pacific atolls (Wiens, 1962). In this account, and in a major review by Stoddart (1969), three features are distinguished: the outer reef, the reef rim, and the lagoon. These are considered below.

### Outer reef

The outer reef of an atoll is near continuous and is generally subject to ocean swell that breaks on all sides (Figure 3). The windward rim of the atoll is generally more continuous than the leeward; for example, the major passages through the reef and into the lagoon are more often on the leeward side of the atoll, as seen in the Tuamotu Archipelago (Guilcher, 1988). In many cases, reef islands are more abundant on the windward reef than on the leeward. In the case of many of the atolls in Kiribati, the leeward margin does not reach sea level, and many

**Atolls, Figure 3** Addu Atoll, the southernmost of the Maldives, showing a near continuous rim around the more exposed margins.

of the larger atolls, such as Tabiteuea and Tarawa have a much better developed eastern windward margin (see Figure 4).

The reef front is steep and rises abruptly from the ocean floor, often from as deep as 4,000 m. Although there is a rain of sediment sourced from the living reefs that cascades down the forereef, many atolls margins are characterized by a steep drop-off which exceeds the angle of repose, indicating that the reef has been built by vertical accretion. Much of the forereef of Mururoa (*Mururoa Atoll*), below 10 m water depth, is at an angle of 45° (Chevalier et al., 1969).

The reef front often has one or more distinct terraces; for example at 15–20 m depth on the reef front of Marshall Island atolls (Emery et al., 1954). The shallow reef front commonly has a prominent spur and groove (*Spurs and Grooves*) morphology (Munk and Sargent, 1954). This consists of broad ridges, covered by coral or coralline algae, which run at right angles to the reef margin, oriented into the dominant wave direction. The ridges are interpreted as constructional, interspersed with sand-filled channels that may be erosional. Spur and groove are best developed on high-energy reef fronts and merge into surge channels at the reef crest (see *Reef Front Wave Energy*).

The reef crest is generally dominated on the windward side of the atoll by a prominent crest, veneered by pink algae (*Porolithon* or *Lithothamnion*) forming an algal rim (*Algal Rims*) on higher-energy trade-wind dominated windward reef crests. Waves break on all sides of an atoll, if the reef reaches sea level, but the largest breakers are on the margin that faces the swell direction.

#### Reef rim

The reef rim can be of variable width and contains islands in some instances, or can be a broad reef flat in others. Typically, the reef flat (*Reef Flats*) is between 100 and 1,000 m wide; many of the north Pacific atolls have an average width of about 500 m (Wiens, 1962). The reef flat is shallow, or commonly much of it may be exposed during lowest tide. In other settings, distinct zones can be discriminated across the upper surface. The algal rim, over which coralline algae are dominant, often merges into a backreef zone that has detrital material on its surface. In the higher energy setting, this is a discontinuous scatter of boulders of dead and detached corals, or fragments of reef limestone. In less exposed sites, such as lower energy atolls rims or the leeward margin of otherwise high-energy atolls, the fragments are smaller and less frequent. Corals thrive in pools of water that remain deep enough over a tidal cycle, and the reef crest and immediate backreef are some of the most productive settings. Turf algae can be abundant and benthic foraminifera are epiphytic on these algae or under loose boulders and within crevices on the reef (Collen and Garton, 2004).

The reef flat that forms on Pacific and Indian Ocean atolls is usually broad and flat. On some atolls a slightly deeper channel may occur behind the boulder zone, usually with thickets of branching *Acropora* and *Montipora* corals, and this has been called the boat channel (*Boat Channel*) as it is adopted as the preferred route to navigate a small boat along the reef rim. If the reef flat is at an elevation that it is exposed during low tide, then the surface is

**Atolls, Figure 4** Several of the atolls in the Gilbert chain, Kiribati, showing a selection of atoll outlines. Tamana is an example of a table reef on which there is a single island on a smaller reef platform.

generally veneered by coralline algae, but deeper pockets enable corals to persist. Where there is sufficient water over the reef top for them to establish, massive corals, particularly of the genus *Porites*, are often limited in their upward growth by exposure during low tide and adopt a microatoll growth form. These microatolls (*Microatoll*) can grow laterally in some cases to several meters diameter. There is also often the distinctive blue octocoral *Heliopora* in this setting. The elevation of the reef flat is critical in determining whether there is suitable substrate for coral to establish, and, as will be discussed below, slight changes of sea level can alter the nature of the habitat on the reef flat. In many cases the reef flat can be interpreted to have formed under a slightly higher sea level, and the gradual fall of sea level over recent millennia has resulted in substrates on which coral previously grew, now being emergent at low tides and no longer suitable for modern corals to colonize. Aerial reconnaissance often reveals a backreef zone that appears aligned, with linear reef-crest normal stripes extending into the lagoon. Whereas this aligned coral zone (*Boulder Zone/Ramparts*) suggests a response by corals to the directions of flow across the reef, such patterning is rarely apparent when actually on the reef flat.

In a number of cases, evidence of a higher former sea level can be seen, such as fossil corals in their growth position (including microatolls that grew at an elevation at which they can no longer grow). On a few atolls mushroom shaped rocks indicate that such a higher surface is being actively undercut (e.g., Mopelia Atoll in the Society Islands), although in a few cases in the Tuamotus these older remnants, termed *feo*, are Pleistocene in age. On a few atolls there is also a fossil algal ridge stranded several hundred meters inshore of the modern algal rim. Fossil algal rims of late Holocene age have been dated on Suvarrow Atoll in the Cook Islands (Woodroffe et al., 1990a) and Nukutipipi Atoll in the Tuamotus (Salvat and Salvat, 1992).

Reef islands develop on many of the reef rims of atolls. The details of these islands are examined below, but one of the most significant features is the degree of continuity along the reef. Where there are no islands, the reef flat extends from reef crest to lagoon. Major passages into the lagoon are significant because they enable significant water exchange between ocean and lagoon; they also interrupt the chain of islands along the rim. The Polynesian term for large and deep passages is *ava*. Smaller and shallower passages between islands are called *hoa* (Figure 5).

**Atolls, Figure 5** Three atolls in the Tuamotu. The *upper* is Kaukura Atoll which is about 48 km from west to east; the *lower*, Haraiki and Tauere Atolls, are both about 7 km from west to east (satellite imagery courtesy of Serge Andréfouët).

The degree to which the lagoon of an atoll is enclosed, and the nature of the passages is a key feature in relation to circulation in, and flushing of, the lagoon (see [Lagoons](#) and [Lagoon Circulation](#)).

Those atolls with numerous or large *ava* are generally effectively flushed by tidal circulation, whereas atolls that have almost continuous reef rims around their perimeter (see Tauere Atoll, [Figure 5](#)) are more likely to be flushed through the action of waves overtopping the reef rim (Callaghan et al., 2006). The nature of flow, and the degree to which sediment is transported through inter-island passages (*hoa*), varies as a function of depth, distance from the reef crest, and tidal and wave energies. Similar passages occur between islands on the rim of Indian Ocean atolls. For example, Guppy (1889) made important observations in the passages that feed the lagoon on the Cocos (Keeling) Islands on the basis of which he made a first estimate of the rate of sediment infill, inferring that the lagoon would require several thousand years to fill with sediment. The significance of these interisland passages has been further examined by Kench and McLean (2004).

Where *hoa* do connect with the lagoon, they can be conduits for sediment transport and a sand apron, comprising material sourced from the reef or reef flat, which

accumulates at the lagoonward mouth of the *hoa*. In atolls that have a large enough lagoon that sufficient wave energy can be generated across the lagoon, these sediments can be further reworked alongshore along the reef island lagoon shores, such that a spit can form, in some cases closing the *hoa* and forming a closed pond known in Polynesia as *tairua*; an example of an atoll where this has happened is Taiaro.

Sheltered locations on the lagoonal shore may be colonized by mangroves; several species of mangroves occur on atolls in the Maldives, and in the Marshall Islands, Kiribati and Tuvalu. Mangroves are absent from the Cook, Tokelau and Tuamotu islands, although introduced to the Society Islands. Mangroves decrease in species abundance from west to east across the Pacific although with a disjunct species *Rhizophora samoensis* occurring from New Caledonia to Samoa (Woodroffe, 1988).

### Lagoon

The lagoon is sheltered in comparison to the outside of the atoll, and may contain scattered patch reefs, which have also been called pinnacles or knolls. Some lagoons

(*Lagoons*) may have few such patch reefs, but in other atolls there can be an intricate mesh of reefs forming a reticulate network of shallow reefs, such as Mataiva (see also *Reticulated Reefs*). The narrow ridges of reef separate deeper holes, termed “*Blue Holes*”. Lagoons vary considerably in depth; they can be shallow, or tens of meters deep (Gischler, 2006). Reginald Daly believed that there was an overall similarity in the depth of many atolls, which he considered provided support for his theory of glacial control (described below, see also Daly). However, it is now recognized that there is considerably more variation in depth than envisaged by Daly. Atolls in the southern Maldives, for example, contain lagoons that are more than 70 m deep, but other lagoons may partially dry at low tide (the southern end of the lagoon of the *Cocos (Keeling) Islands*, for example).

The lagoon is a prominent feature of most atolls. Lagoons are gradually infilling both with sediment produced within the lagoon, but more especially with sediment derived from the more productive reef rim. Purdy and Gischler (2005) propose an “empty bucket” model of lagoon infill, capturing the stages of infill after the surrounding reefs have caught up with sea level (Neumann and Macintyre, 1985). The pattern of infill is likely to depend on the nature of the reef rim, and sediment production may be proportional to the atoll’s perimeter (Tudhope, 1989).

The lagoon at Enewetak has been described in a detailed study by Emery et al. (1954). It reaches a depth of 55 m, and the benthic communities form a series of concentric zones (Colin, 1986), with foraminifera a conspicuous component of lagoon sediments, and a patch reef zone (termed knolls or pinnacle reefs by Emery) (Wardlaw et al., 1991). Similar concentric zones are known to occur in the sediments of Rongelap and Bikini Atolls (Emery et al., 1954) and also in the case of Kapingamarangi Atoll (McKee et al., 1959). More recent studies reaffirm the significance of foraminifera, particularly *Calcarina* and *Heterostegina* in each of Kayangel in the Palau Islands, and Enewetak and Majuro in the Marshall Islands (Yamano et al., 2002). There is much variability in the lagoon floor sediments of Tarawa Atoll, in Kiribati, but foraminifera are a prominent component (Weber and Woodhead, 1972; Lovell, 2000; Paulay, 2001). The calcifying alga *Halimeda* is one of the most prominent features of the sediments of some of the deeper lagoons; it dominates much of the interior of the lagoon of Suvarrow (Tudhope et al., 1985). In the case of Cocos, much of the lagoon is dominated by sediments produced within the lagoon (Smithers et al., 1992). Mud may accumulate in localized embayments within the islands, termed *teloks* on Cocos and *barachois* on Diego Garcia (Stoddart, 1971). On highly enclosed atolls, such as Marakei in the Gilbert chain of Kiribati, lagoon sediment is mud, with reef flat foraminifera found only at the entrance to the narrow reef passage on the eastern margin (Woodroffe, 2008). Mud is typical of the lagoon floor within the reticulated reefs of Mataiva Atoll in French Polynesia (Adjas et al., 1990).

Although active vertical reef growth implies that the reef rim might be a constructional feature, it has been apparent since the study of MacNeil (1954) that solution of the interior of the lagoon occurs during subaerial exposure when the sea is lower than present during glaciations. This view, examined further below in relation to the geological evolution of atolls, has been especially promoted by Purdy and Winterer (2001).

The geomorphology and biogeography of atolls has been mapped in detail where ground reconnaissance has been undertaken, notably through the extensive studies of David Stoddart (*Stoddart, David Ross (1937–)*), or in a few instances where aerial photography is available at suitable scales (Woodroffe and McLean, 1994). Recently, high-resolution satellite imagery has been used in conjunction with state-of-the-art remote sensing algorithms to map reef geomorphology and habitat distribution (Andréfouët et al., 2001, 2003; Naseer and Hatcher, 2004; Yamano et al., 2006).

### Geological evolution of atolls

As the oceans were explored during the seventeenth and eighteenth centuries, atolls became more broadly known. We do not know when atolls first became a feature of familiarity to European explorers, but they have certainly been known since the Spaniard Mendana landed on an atoll in Tuvalu. In the early nineteenth century, Charles Lyell (*Lyell, Charles (1797–1875)*) promulgated the view that atolls represented a coral veneer around the margin of submerged volcanic craters, in his *Principles of Geology* published in the 1830s, a book that was to have a profound influence on Charles Darwin.

Charles Darwin (*Darwin, Charles (1809–1882)*) proposed an alternative theory, his theory of coral reef formation, after witnessing evidence of the vertical movement of land during surveys by *HMS Beagle* on the coast of South America. Darwin’s subsidence theory considered that there “is but one alternative; namely the prolonged subsidence of the foundations on which the atolls were primarily based, together with the upward growth of the reef-constructing corals. On this view every difficulty vanishes; fringing reefs are thus converted into barrier reefs; and barrier reefs, when encircling islands, are thus converted into atolls, the instant the last pinnacle of land sinks beneath the surface of the ocean” (Darwin, 1842, p.109). This remarkable deduction that volcanic islands in mid-ocean might undergo subsidence, and that reefs might proceed through a sequence from fringing reef to barrier reef to atoll, as a consequence of vertical reef growth to sea level, had occurred to Darwin after observing the evidence of uplift in South America, before he ever saw a reef. His hypothesis was reinforced when he viewed the fringing reefs around Moorea from the slopes of Tahiti. Although the *Beagle* passed atolls in the Pacific, it did not stop at any. Darwin wrote the first draft of his theory of reef development as the ship sailed to New Zealand (Stoddart, 1995). The *Beagle* had passed through the Tuamotu Archipelago in what is now French Polynesia, but the only atoll

that Darwin set foot on was the Cocos (Keeling) Islands in the eastern Indian Ocean. Here he keenly accepted observations of the undercutting of coconuts and the erosion of the shoreline as “tolerably conclusive evidence” in support of his theory.

It is important to discriminate that Darwin’s theory applies to the *structure* of reefs, based on their long-term evolution, at timescales of millions of years, whereas the *surface morphology* of the atolls reflects late Holocene formative processes that operate over much shorter timescales (Stoddart, 1973b). Stoddart (Stoddart, David Ross (1937–)) has emphasized the difference in time scale; reef structure (*Reef Structure*) being the outcome of millions of years of geological evolution, whereas the surface morphology results from the most recent (Holocene) adjustments of form to the processes that operate, including subtle changes in sea level. At the time Darwin proposed his theory, the significance of sea-level fluctuations associated with the glaciations was unknown, but it is possible to incorporate our latest understanding of the oscillations of sea level into the gradual formation of the sequence of limestones that underlie a typical atoll.

Darwin’s subsidence theory of atoll evolution was tested by deep drilling on *Funafuti Atoll* in 1896–1898 which, although it failed to reach the underlying volcanic basement, recovered more than 300 m of shallow-water carbonates implying subsidence (Spencer et al., 2008). Subsidence of volcanic basements upon which atolls are founded was eventually substantiated by drilling on the atolls of Bikini and Eniwetak in the Marshall Islands (see a synthesis in Guilcher, 1988, and *Bikini Atoll, Marshall Islands; Eniwetak Atoll, Marshall Islands*). Daly recognized the significance of sea-level fluctuations (Daly, 1934) and documented evidence from across the Pacific that recorded a sea level above present level. However, the *Glacial Control Hypothesis* that Daly advocated to explain reef development, further developed by Wiens (1959, 1962), presumed that reefs were totally planed off at low sea level and that the entire structure of modern reefs was Holocene. The antecedent karst hypothesis advocated by Purdy (1974) corrected this mistaken view, and recognized the significance of *Antecedent Platforms*, often of late Pleistocene age. It has now been widely shown that the reef rim on modern atolls is underlain by older Pleistocene reefs (McLean and Woodroffe, 1994; Montaggioni, 2005).

Darwin’s theory was enthusiastically adopted by several other prominent scientists, most notably Dana (Dana, James Dwight (1813–1895)), and became widely debated. An alternative view proposed by Murray (1889) revolved around a belief that atolls developed as a result of solution of lagoons. Although considered by Gardiner (1931), this view became discredited when it was realized that seawater was supersaturated with calcium carbonate. Wood-Jones (1912) proposed an alternative view based on his time in the Cocos (Keeling) Islands. He thought that it was the production of sediment around the margin of an atoll and its transport and deposition in the interior that prevented coral growth in the center of reef platforms. However, this

sedimentation theory was not widely supported. W.M. Davis (Davis, William, Rorris (1850–1934)), in his review of the origin of reefs (Davis, 1928), considered that the only real contender against Darwin’s view was the glacial control theory proposed by Daly, and in a subsequent review, Cotton (1948) regarded the subsidence, glacial control and antecedent topography theories as plausible.

In addition to his observations on Cocos, Darwin undertook a substantial compilation of information on reefs, and in his book published in 1842, he included a map of the distribution of atolls, which provided further evidence of the fact that most atolls occur in mid ocean (Darwin, 1842).

Further exploration was to extend knowledge about atolls. The distinguished American geologist, James Dana, extended Darwin’s ideas as a result of his visits to Kiribati, Tuvalu, the Tuamotu Archipelago, the Society Islands, Fiji, and the Phoenix and Hawaiian Islands. He was a firm supporter of the subsidence hypothesis (*Subsidence Hypothesis of Reef Development*). Alexander Agassiz (Agassiz, Alexander (1835–1910)) undertook extensive studies of reefs on extended voyages at the turn of the twentieth century. His 9-month cruise on *Albatross* in 1899–1900 enabled him to describe 30 atolls in the Tuamotu Archipelago and 28 in Tuvalu, and the Marshall and Caroline Islands. He followed this with further descriptions of the Maldives Archipelago in 1901–1902, where his observations built on those of Gardiner who had mounted an expedition in 1899–1900. Agassiz attempted to drill Wailangilala atoll in Fiji, but recovered material only from the upper 26 m. The Chagos Archipelago was described during the Percy Sladen expedition, and a fuller account of this period of reef exploration is given by Spencer et al. (2008). The *Cocos (Keeling) Islands* were examined by Guppy (1889); Wood-Jones (1912); and Gibson-Hill (1947), making this one of the best known atolls by mid-twentieth century.

Darwin had realized that drilling through an atoll was the optimal way to test his theory and he wrote before his death to Agassiz in an effort to encourage such drilling (see *Darwin, Charles (1809–1882)*). Such drilling was finally undertaken on Funafuti Atoll. The *Royal Society of London* sponsored a program involving a series of expeditions in the 1890s to Funafuti. The objective was to drill the perimeter of Funafuti to test Darwin’s theory of reef development. The initial fieldwork was led by Professor W. Sollas in 1896; further drilling was undertaken in 1897, together with field mapping by T. Edgeworth David (David, Tannant Edgeworth (1858–1934)) and George Sweet, and the final stage of drilling, although still in shallow-water carbonates, was overseen by Alfred Finckh in 1898. At the time the fact that the core did not reach volcanic basement at more than 300 m depth appeared inconclusive, although it was clear that shallow-water carbonates persisted below depths at which they are now forming. In retrospect we now know from the strontium isotope stratigraphy that dolomite in the lower core was formed through diagenesis between 1 and 2 million years ago. The upper 26.4 m of the core has been radiocarbon

dated indicating a history of sea-level rise during the past 8000 years (Ohde et al., 2002).

During the Quaternary, atolls have evolved in response to a series of sea-level oscillations. It was Daly who gave these Quaternary ice ages such prominence in geological interpretations of oceanic islands. His glacial control theory involved the eradication of coral reefs from areas at their poleward limits, which he called marginal seas during successive glaciations (although this view is not supported by study of reefs at their latitudinal limit). He also believed that the reef rim had been planed off during glacial lowstands, and by inference that the entire reef rim had accreted during the postglacial. Daly's views were further promoted by Wiens (1959, 1962), but are no longer supported (see *Glacial Control Hypothesis*).

Significant further studies on atolls occurred after World War II. American research in the Pacific involved a focus on the atolls of the Marshall Islands. Geological studies were prominent and the stratigraphy of atolls became better known because of selection of sites for atomic bomb testing, as well as through scientific curiosity. Seismic studies in 1946 and 1950 provided the first hint that the carbonates were underlain by volcanic rocks (Raitt, 1954), together with the recovery of noncarbonate rocks dredged from depths greater than 1,400 m on the flanks of these islands. In 1951, drilling on Bikini Atoll encountered basalt at depths of 1,287 and 1,411 m respectively in two boreholes. Examination of the limestones indicated that they had been deposited in shallow water, and the presence of solutional unconformities supported the episodic exposure of these during successive sea-level lowstands (Schlanger, 1963).

Subsequently drilling on Mururoa has revealed 400–500 m of carbonate over the volcanic basement that underlies that atoll (q.v.), with a similar stratigraphy also on neighboring Fangatafu (Lalou et al., 1966). A Quaternary history of the past 300,000 years has been derived (Camion et al., 2001) implying that the atolls became more atoll-like as a result of dissolution of the lagoon and buildout of the periphery through reef growth. On Midway Atoll in the Hawaiian Islands (*Midway Atoll (Hawaiian Archipelago)*), volcanic basement has been encountered at 55 m beneath Sand Island and 378 m beneath reef to the north of the lagoon, further supporting Darwin's subsidence theory (Ladd et al., 1967, 1970).

A series of further studies were initiated by the Pacific Science Board during the period 1946–1969. This included fieldwork on Arno, Ifaluk and Kapingamarangi Atolls in what are now the Federated States of Micronesia, Onotoa in Kiribati, and Raroia in French Polynesia. A compilation of this work led to the publication of the book on atolls by Wiens in 1962. This was also a period during which the Atoll Research Bulletin was initiated (Fosberg and Sachet, 1953; Spencer et al., 2008).

### Quaternary evolution of atolls

Shallower drilling on several atolls has encountered Pleistocene reef limestone, often dated to the Last Interglacial, at

depths of 10–20 m below the modern atoll rim. In the Cocos (Keeling) Islands Pleistocene limestone, shown to be of Last Interglacial age, occurs at depths of 8–13 m below sea level beneath each of the major islands, and seismic reflection profiling records a reflector that correlates with this discontinuity beneath the lagoon (Searle, 1994; Woodroffe et al., 1994). This karstified Pleistocene limestone underlies the rim composed of Holocene limestones. Pleistocene limestone has been shown to underlie the rim of Tarawa Atoll (Marshall and Jacobson, 1985), Funafuti Atoll (Ohde et al., 2002), several atolls in the northern Cook Islands (Gray et al., 1992), as well as atolls in the Maldives and Chagos Archipelagoes (Woodroffe, 2005). In some that have been drilled to deeper depths, such as Eniwetak and Mururoa, it is apparent that the last interglacial limestone is underlain by older reef limestones deposited during preceding highstands (Szabo et al., 1985; Camoin et al., 2001).

When sea level was high during the last interglacial (and presumably former interglacials) an atoll rim similar to the modern existed, although no evidence remains as to whether it contained islands (Perrin, 1990). During glaciation the reef limestones were exposed by the lower sea level, and the emergent limestone underwent solution (karstification). Atolls appear to be undergoing gradual subsidence associated with plate migration (Scott and Rotondo, 1983, see *Subsidence Hypothesis of Reef Development*), so when sea level rose again during postglacial times it flooded the platform around 8000 years ago. There are several atolls on which last interglacial limestone is exposed at the surface (e.g., Aldabra in the western Indian Ocean, Braithwaite et al., 1973; Anaa in French Polynesia, Pirazzoli et al., 1988; and Christmas Island in eastern Kiribati, Woodroffe and McLean, 1998). The extent to which lowering and reshaping of the surface results from subsidence or from solution remains an issue of debate (Purdy and Winterer, 2001, 2006); erosion appears to have accentuated lagoon morphology on many atolls.

### Accretion of the reef rim

Holocene reef growth has been constrained by the pattern of sea-level change; there appears to have been a lag before corals reestablished over the Pleistocene substrate around 8000 years ago. The reef grew in an effort to catch-up with sea level, as revealed in the case of Cocos in the Indian Ocean (Woodroffe et al., 1994) and Tarawa in the Pacific Ocean (Marshall and Jacobson, 1985). After reefs caught up with sea level, lateral progradation of the reef seems to have occurred, particularly in those situations such as Suvarrow and Nukutipi where there are fossil algal rims abandoned behind the modern reef crest.

The majority of polar ice melt appears to have been completed by 6000 years ago, and the volume of water in the ocean at that time is likely to have been similar to that of today. However, hydro-isostatic adjustments mean that the details of relative sea-level history vary geographically (Lambeck, 2002, see *Mid Holocene*). In particular, a fall of sea level occurred relative to far-field

remote islands, which has been termed ocean siphoning (Mitrovica and Peltier, 1991). Whether the sea-level curve at far-field sites peaked abruptly around 6000 years ago and fell since then (through ocean siphoning) or whether there has been post-6000 year melt, with a more gradual peak around 4000 years is difficult to discriminate from atolls, because it was necessary for the reef rim to accrete to sea level before evidence would be preserved (Nunn and Peltier, 2001). The atoll rims have grown from the surface of the Pleistocene limestone to catch up with sea level, so the timing of the initiation of a reef flat in mid Holocene varies geographically from atoll to atoll. Hydro-isostatic adjustments mean that the elevation of mid-Holocene reefs can also vary between atolls.

The conglomerate platform on some atolls contains within it evidence of corals in growth position that formed a part of a former reef flat (see *Conglomerates*). Fossil microatolls are especially useful in this respect, but other reef flat corals such as *Heliopora* can also be important in differentiating units within the conglomerate platform that mark former reef flat surfaces and indicate higher than present sea level, and overlying storm deposits. Radiocarbon dates on corals from conglomerate record inputs of corals detached during storms. For example, ages of 4000–3000 years BP have been obtained on corals from within the conglomerate platform on the Cocos (Keeling) Islands (Woodroffe et al., 1994). Ages from other atolls seem broadly comparable, with evidence for variation in Kiribati-Tuvalu (the Gilbert-Ellice chain), from north (where it may have been as old as 4000 years ago) to south (where reefs may have reached sea level since 2000 years ago, McLean and Hosking, 1991). Radiocarbon ages as old as 5500 years BP have been reported from atoll surfaces in the Tuamotu Archipelago (Pirazzoli and Montaggioni, 1988).

Since the reef rim reached sea level and the reef flat was formed, there has been further carbonate sediment produced which has continued to infill the lagoon (Purdy and Gischler, 2005) and has seen the accumulation of sediments to form reef islands around the margin. Several researchers suggested that island formation on atolls occurred as a result of this slight fall of sea level (Cloud, 1952; Schofield, 1977a, b; Dickinson, 2004).

David and Sweet (1904) undertook mapping of the islands and reef flats around *Funafuti Atoll*, and considered that large *Porites* corals in growth position indicated that the sea had been above its present level relative to the atoll in the past. Similarly Cloud (1952) described outcrops of *Heliopora* in growth position, above the elevation that it presently reaches on the reef flat as evidence of emergence on Onotoa. There has been an ongoing debate about the extent to which conglomerate of this type is formed by storms. An expedition to the Caroline and Marshall Islands (CARMARSEL expedition) specifically to resolve whether the conglomerate was a storm deposit or as an indicator of higher sea level reached no consensus (Shepard et al., 1967; Newell and Bloom, 1970). The most

accurate reconstructions of former sea level have been derived where a fossil sea-level indicator can be related to its modern equivalent (see *Sea-Level Indicators*), and the two most appropriate types of indicator are microatolls of massive coral and reef flat outcrops of *Heliopora*.

Outcrops of conglomerate have been used to infer higher sea level in the Maldives (Gardiner, 1903; Sewell, 1936), but the evidence is fragmentary. Dated *in situ* coral from Addu Atoll was interpreted to infer that the reef flat had reached modern sea level by around 3000 years BP (Woodroffe, 1993). Two recent subsequent studies have proposed detailed sea-level curves for the Maldives during the Holocene, but differ on whether or not it is possible to identify evidence to support sea level higher than present in mid Holocene (Gischler et al., 2008; Kench et al., 2009). Based on detailed mapping of conglomerate around Cocos, several *in situ* microatolls have been radiocarbon dated and indicate that there has been a gradual fall of sea level from an elevation 0.5–0.8 m above present over the past 3000 years (Woodroffe et al., 1990b; Woodroffe, 2005).

In the case of islands in the Pacific Ocean there has been a similar debate. The radiocarbon ages reported by Schofield (1977a) from Kiribati and Tuvalu appear to be from corals from the conglomerate that were not in their growth position. The conglomerate in the northern part of the Gilbert chain is composed of a lower unit that contains *Heliopora* in its growth orientation at a few localized sites (Falkland and Woodroffe, 1997; Woodroffe and Morrison, 2001), overlain by an upper unit of disoriented cemented coral clasts. There have been several attempts to infer sea level either geographically (Grossman et al., 1998) or at a site (e.g., French Polynesia, Pirazzoli et al., 1987; Pirazzoli and Montaggioni, 1986, 1988; Funafuti, Dickinson, 1999), but these have not discriminated the *in situ* corals from the more extensive larger conglomerate outcrops. Large sea-level oscillations or abrupt changes appear unlikely, and studies that identify large anomalous fluctuations of sea level have generally been rebutted. For example, evidence for an abrupt fall of sea level around 1300 AD inferred by Nunn (1998) has been criticized by Gehrels (2001) both on the basis of how dating evidence was handled as well as because evidence from a wide geographical area is brought together without regard to spatial variability.

### Reef islands on atolls

A generalized cross-section of an atoll reef island suggests a typical cross-island morphology comprising a distinct oceanward ridge and a lesser lagoonward ridge, with a pronounced swale in the middle. Figure 6 demonstrates considerable variation in reef island morphology, as well as human modification. Waves represent the principal processes that build islands. Open ocean swell is filtered at the reef crest, but a component of the wave energy crosses the reef flat and reaches the island shore. As a consequence,

**Atolls, Figure 6** Reef island cross sections surveyed across a selection of atolls and illustrating the variability in surface topography. Several of the reef islands have been modified through the excavation of pits for cultivation of taro.

reef islands are low-lying; on many Pacific atolls, and also on the Cocos (Keeling) Islands, only about 33% of the reef island surface is more than 2 m above mean sea level, and <8% exceeds 3 m above mean sea level. In the Maldives the islands appear even lower, with around 4 and 1% of the total island area above 2 and 3 m above mean sea level, respectively (Woodroffe, 2008).

#### Island sediments

Atoll reef islands are built from sediments that are entirely calcareous, being derived from the skeletal fragments of organisms living on the reefs, such as coral, coralline or calcifying algae, molluscs, and foraminifera. Genera of benthic foraminifera, such as *Calcarina*, *Amphistegina* and *Baculogypsina*, produced on the reef crest and the reef

flat close to the crest, are a major contributor to the sands from which the islands are composed in Kiribati, Tuvalu, and the Marshall Islands (Woodroffe and Morrison, 2001; Collen and Garton, 2004; Fujita et al., 2009). Elsewhere islands may be composed of coarser material, including coral rubble and shingle. Islands composed of coarser material are often referred to by the Polynesian term *motu* (*Atoll Islands (Motu)*) and differentiated from sandy islands that are called cays (Stoddart and Steers, 1977).

Prominent on many atolls is a conglomerate of disoriented coral blocks, often forming a platform that represents highly resistant substrate where it occurs. Many reef islands appear to be anchored on such outcrops of conglomerate (Montaggioni and Pirazzoli, 1984). Although disoriented coral boulders and cobbles give the conglomerate an irregular appearance, the upper surface is often relatively horizontal, and internal structure may contain distinct beds of various thicknesses. The conglomerates are cemented by coralline algae and marine cements such as isopachous rims of fibrous aragonite or high-magnesian calcite.

Less well-lithified outcrops around the margins of islands include beachrock, which is cemented beach sand, preserving the dip of the original beach. The sands appear to have been cemented beneath the water table, and beachrock may be preserved where sand has been eroded away, indicating former shoreline positions. Cay sandstone is a less well-cemented limestone; this poorly lithified carbonate is horizontally bedded and seems to form associated with the water table within the island interior. On a few islands, the droppings of nesting seabirds have infiltrated into sands in the island interior and they are cemented with a phosphatic cement (Rodgers, 1989). Island surfaces can also be colonized by vegetation, which contributes both directly through roots that stabilize sand and humus that gives the soil greater structure.

Morphological differences have been identified between atolls in storm-prone areas, and those closer to the equator where tropical cyclones (typhoons, hurricanes) are not experienced. Where storms are frequent, reef flats contain abundant coral rubble and large blocks of reef limestone called reef blocks (Bayliss-Smith, 1988). For example, megablocks (*Megablocks*) up to 4 m high and 10 m long were reported to have been deposited on the reef flat of Nukutipipi Atoll in the Duke of Gloucester group in the Tuamotu Archipelago, by the cyclones Veena and Orama that occurred in 1983 (Salvat and Salvat, 1992). Significant impacts were observed after a storm on Jaluit (Blumenstock, 1961). Under some circumstances it appears that tsunamis may detach and emplace large blocks of similar dimensions on coral reefs (Bourrouilh-Le Jan, 1998), but as a tsunami has only a small amplitude in mid ocean, the prevailing view is that these megablocks are emplaced by cyclones. Rubble ramparts are often formed by individual storms (Scoffin, 1993); for example the “Bebe” bank on Funafuti (Maragos et al., 1973; Baines et al., 1974). This rampart has been gradually reworked shoreward across

the reef flat, since it was thrown up during Cyclone Bebe, and in places it has accreted onto similar, but earlier storm-derived deposits on the reef islands (Baines and McLean, 1976). Where storms are less frequent, boulders may accumulate and contribute to a conglomerate that underpins the island. In those atolls closest to the equator and outside the storm belt, such as the Maldives, the islands are predominantly built of sand. Boulder ramparts (*Boulder Zone/Ramparts*) and shingle ridges (*Shingle Ridges*) are indicators of former storm events, and may be eroded and only partially preserved (Pirazzoli, 1987). Rubble storm ridges, deposited over the past 3000 years, are prominent features on islands in Lakshadweep (formerly the Laccadives) to the north of the Maldives (Siddique, 1980).

### Processes of island formation

Almost all material which comprises reefs islands is amenable to radiocarbon dating, and a series of models of reef-island formation on atolls was proposed by Woodroffe et al. (1999). Radiocarbon ages yield estimates of the time of death of skeletal organisms, and deposition may occur some time later, after an undefined period of transport, breakdown, erosion, and redeposition. However, a pattern of gradual oceanward accretion of reef islands appears to have occurred on an elongate island (West Island) on Cocos (Woodroffe et al., 1999), and on Makin at the northern end of the Gilbert chain in Kiribati (Woodroffe and Morrison, 2001). These, and results from comparison of multitemporal aerial photography or satellite imagery (Webb, 2006), indicate ongoing accretion, where sediment production and transport are sustained, on many of the oceanward shores of atoll islands. In other settings there may be more complex trends in shoreline erosion and deposition (Richmond, 1992). For example, detailed resurveys of beaches on the islands of Betio and Buariki in South Tarawa indicate fluctuations of island outline that correspond with wind changes associated with the El Niño-Southern Oscillation phenomenon (Gillie, 1993; Solomon and Forbes, 1999), and in the Maldives seasonal adjustments follow reversal of the monsoon (Kench et al., 2006). An alternative model of island build-up has been proposed for the small sandy islands that occur on patch reefs in the center of the lagoons on atolls in the northern Maldives (Kench et al., 2005). A further approach to determining island formation has been recently developed with the use of computer modeling (Barry et al., 2007, 2008).

### Island soils, vegetation, and ecosystems

The calcareous sediments that form reef islands on the margin of atolls produce poorly developed and immature soils (Morrison, 1990). Soil characteristics depend primarily on the incorporation of plant matter and the development of a humus layer. An exception is the occurrence of phosphate-rich areas, first identified by Fosberg (1957), but subsequently described in several situations where the vegetation is, or was previously, dominated by the tree *Pisonia grandis*. This tree attracts seabirds

and the phosphate enrichment appears related to bird guano.

In contrast to neighboring high islands, the atolls and low islands of the Indian and Pacific Oceans have a relatively species-poor flora. There is a distinct pantropical group of plants that are dispersed effectively across large distances. Many of these plants are strand plants that have seeds that float and can be easily washed up on the beaches around the margins of atolls. Early descriptions of the vegetation and floristics of atolls were undertaken by Raymond Fosberg (1974, 1992), and a major compilation on the vegetation of the tropical Pacific outlines the principal vegetation associations (Mueller-Dombois and Fosberg, 1998).

Several creepers can occur on the beach, such as *Ipomoea pes-caprae* and *Vigna marina*. A coastal fringe of shrubs develops on those sand cays that are not ephemeral, and a broad belt of *Scaevola taccada* and *Suriana maritima* is frequent, often with *Tournefortia argentea* (*Argusia [Messerschmidia] argentea*), which can grow into a small tree. On the larger islands a peripheral belt of shrubs often grades into a forest with trees such as *Cordia subcordata*, *Calophyllum inophyllum*, *Hernandia peltata*, *Guettarda speciosa*, and *Pisonia grandis*. On many atolls the interior is covered with coconut woodland, but in most cases this has been planted and is maintained because the coconut (*Cocos nucifera*) is important for subsistence and often as the basis of a commercial copra industry. A zonation with increasing maturity of vegetation and soils into the interior of reef islands can be recognized, often representing a temporal succession (see [Coral Cays, Vegetational Succession](#)).

The smaller islands tend to contain the least species, and the relationship between number of plant species and island area, particularly based on a study of the vegetation of Kapingamarangi Atoll (Niering, 1963) provided support for the development of ideas on island biogeography by MacArthur and Wilson (1967). However, it is also apparent that the smallest islands, particularly those less than 100m wide, are too small to support a freshwater lens, and only have a restricted strand flora (Whitehead and Jones, 1969). Although on predominantly sandy reef islands there are more species on the larger islands, two further factors are important. On the remote atoll of Suvarrow in the Cook Islands, it is evident that plants are influenced by the substrate, with extensive stands of *Pemphis acidula* sprawled across outcrops of conglomerate (Woodroffe and Stoddart, 1992). Mangrove habitats are also restricted in extent to those few locations where it is sheltered and there is brackish water. Mangroves may occur around the margins of a lagoon (e.g., on Nui in northern Tuvalu, or in the more enclosed embayments as in Vaitupu, Tuvalu, and can also be found in completely enclosed depressions in the center of table reefs, such as Nanumanga, Tuvalu) (Figure 7). On the islands with settlements there are generally many introduced plants (Woodroffe, 1985), including crops such as breadfruit (*Artocarpus*), pandanus, banana and taro (*Calocasia*,

*Cyrtosperma*) and ornamentals, such as the frangipani (*Plumeria*) (Dawson, 1959). Giant taros provide the traditional staple food and are planted in excavated pits. These pits are dug until ground water level is reached. Taros are planted just above the groundwater level and surrounded by woven coconut fronds or pandanus leaves that provide a retaining wall for the plant compost.

On the most remote atolls, where human visitation is minimal, reef islands can support huge colonies of seabirds. Noddy and sooty terns, boobies, and frigate birds nest in enormous numbers, and if unused to human presence, sit unconcerned while the occasional visitor wanders amongst them. Typically, the ecosystems which develop on atolls are composed of widespread easily dispersed species, and there tends to be a low degree of endemism, presumably because islands have only appeared in the past few millennia on most atolls. Land birds are generally few in number, although there are flightless rails on several atolls. Endemic species are found where the atoll has remained emergent over glacial-interglacial cycles, and not undergone complete submergence during the postglacial sea-level rise. Aldabra in the western Indian Ocean is a noteworthy example with its population of giant tortoises (Arnold, 1976; Stoddart, 1984).

### Atoll hydrology

The small reef islands around the margin of atolls rarely contain freshwater lakes (e.g., Washington in the Line Islands). However, rainwater percolates through the soil and can accumulate as a freshwater lens beneath the island surface. The freshwater lens floats above seawater, and has been characteristically described by the Ghyben-Herzberg principle, that is that the surface elevation of the lens extends above the level of the sea by about 1/40 of the depth to which the lens occurs. The characteristic shape of a Ghyben-Herzberg lens is rarely actually found beneath reef islands because of significant variations in the degree and extent of lithification of the reefal material and in porosity of the limestone (see: [Coral Cays-Geohydrology](#)). A dual aquifer model has been proposed which recognizes the significance of the greater porosity of the Pleistocene limestone that is found beneath the rim of most atolls (Buddemeier and Oberdorfer, 1986). The hydrogeology of several atolls is summarized in reviews by Falkland (1991) and Vacher and Quinn (1997). The elevation of the surface topography influences the water level, and the shape of the lens can also be constrained by well-cemented conglomerate, which may confine the aquifer, as seen in the example of the island of Deke on Pingelap Atoll (Figure 8) in the Marshall Islands (Ayers and Vacher, 1986).

### Human impacts on atolls

The formation of habitable reef islands occurred in mid Holocene, as described above. The history of human occupation therefore is also restricted to the late Holocene, and depends on sea-level history and the accretion of islands

**Atolls, Figure 7** Three atolls in Tuvalu, showing distribution of mangrove and *Pemphis*, and the degree that these environments are impounded (after Woodroffe, 1988).

of suitable size to colonize. In the case of remote atolls in the Pacific, this is often marked by the appearance of *Lapita* pottery (Bellwood, 1987; Weisler, 1994; Nunn, 1999). Human occupation has shaped atoll ecosystems in a number of ways. The vegetation of many has been modified with the planting of coconut plantations, and the introduction of plants as described above.

Human activities have had the greatest impact where there are high population densities (See *Mining and Quarrying of Coral Reefs*; *Engineering on Coral Reefs with Emphasis on Pacific Reefs*). Impacts have affected corals and other carbonate producing organisms. Corals suffer mortality when smothered by sediment (Zann, 1982). Seawater contamination is indicated by increased nutrient levels. Sewerage contains nutrients, and contamination of seawater is often measured by using coliform counts. Increased nutrients can cause localized coral mortality as observed by a high incidence of dead corals on the oceanward reef flat in front of Bikenibeu, a densely populated island on the southern rim of Tarawa Atoll, which has received sewerage outfall in the past (Lovell, 2000).

Domestic waste poses a further threat to ecosystems on some atolls. Certain macrofauna located in the shallow areas of the lagoon at Tarawa may have been organically enriched from land-based anthropogenic sources (Kimmerer and Walsh, 1981; Newell et al., 1996). Also, direct disposal of raw sewerage into the sea has likely increased the seawater nutrient level causing bacterial contamination of the lagoon seawater at Tarawa, but the lagoon ecosystem has been flourishing as a result (Kelly, 1994).

On atolls such as those in the Marshall Islands, Funafuti in Tuvalu and Tarawa in Kiribati increasing population pressure has led to houses being built in inappropriate locations, such as near active beaches and on low-lying areas. In South Tarawa this has prompted the construction of coastal protection structures to avoid overtopping during storms and high water events. There are a large number of reclamations of varying designs and materials built to expand the land area (Figure 9). Betio, Bairiki, and Bikenibeu, the administrative centers of Kiribati, have grown significantly compared to the comparatively pristine islands of Buariki and Abatao on the same atoll,

**Atolls, Figure 8** The atoll of Pingelap, Micronesia, showing a cross-section of Deke Island, and the elevation of the island and the surface elevation of the freshwater lens (after Ayers and Vacher, 1986).

with reclamations and seawalls (both Government and private). Causeway construction between reef islands can have negative physical and biological, as well as social, effects. The position, length, construction method, width of the reefs, and the pattern of water exchange and current strengths mean that causeways can have an influence on both water and sediment transport.

Seawalls pose particular problems. Many are temporary structures built to protect land or expensive assets from erosion. On Tarawa and in the Marshall Islands, they are generally built of coral boulders and beachrock on the margin of land and often extend out onto or across the active beach. Where vertical walls are constructed, these tend to reflect wave energy and can cause scouring

at their base and undercutting (Figure 9). Alternatively, wave overtopping causes infiltration of water leading to structural collapse.

Reclamation and backfilling with sand have provided many people with extra space on small reef islands. Reclamations act like groynes blocking sediment transport along active beaches, with sediment accumulating on the updrift side of structures, while the downdrift side experiences coastal erosion as has occurred on Majuro Atoll (Xue, 2001). Other disturbances to sediment transport pathways can also have severe implications, for example, boat channels, blasted or excavated across the reef flat to provide access for boats at all stages of the tide, also provide conduits for beach sand to be lost over the reef edge.

**Atolls, Figure 9** Human impacts on atoll shorelines, illustrated with examples from Tarawa Atoll, Republic of Kiribati: top left, Oceanside seawall at Nanikai, which reduces access to the ocean; top right, private reclamation; lower left, large reclamation for Mormon Church, Bairiki; lower right, private reclamation that has resulted in erosion of shoreline.

This and similar interventions further disrupt longshore sediment transport, as has occurred on Fongafale, on Funafuti Atoll in Tuvalu (Yamano et al., 2007).

The scarcity of building materials has led to people extracting beach sand and aggregates in large quantities for construction on atolls with a large population. These demands represent a further disruption to the sediment budget causing detrimental impacts such as coastal erosion. On Majuro, chronic erosion has been experienced along lagoonal shores due largely to beach mining (Xue, 2001). Similarly in Vaitupu, Tuvalu, increased sand mining activities in the intertidal zone have reduced beach berm levels, increasing the island's vulnerability to cyclones.

Perhaps the most serious impacts of human activities are yet to be experienced. The impacts of climate change, and in particular sea-level rise, appear particularly ominous for atolls (McLean and Tysban, 2001; Nicholls et al., 2007). There have been several assessments of the vulnerability of atoll reef islands to sea-level rise (e.g., Roy and Connell, 1989, 1991; Lewis, 1989, 1990). Studies of the regional pattern of sea-level rise indicate that the sea is rising with respect to most atolls (Church et al., 2006). The principal

impacts anticipated fall into three categories: shoreline erosion, inundation and flooding, and saline intrusion into the water table (Mimura, 1999). Widespread flooding in the interior of Fongafale on Funafuti Atoll in Tuvalu is often cited as evidence of the effects of sea-level rise, or confirmation that the "islands are sinking" (Pittock, 2005; Patel, 2006). However, Yamano et al. (2007) reconstructed historical conditions showing that the interior of this island was already subject to flooding at the time of the Royal Society expedition in the 1890s. They indicate that construction of an airstrip over former mangrove wetlands further increased the area subject to inundation, and that a considerable degree of human modification, including urbanization, has exacerbated the problem in this instance. Settlement in this densely populated part of the administrative center has encroached on low-lying areas or depressions excavated during military operations (Yamano et al., 2007).

Reef islands are particularly low-lying, although there is considerable geomorphological variability around the margin of any one atoll (Woodroffe, 2008). Islands exhibit a degree of physical resilience, and many may be continuing to build as further sediment is produced through the

growth of calcareous organisms on surrounding reefs and as that sediment is transported onshore. Those parts of atolls that are most resilient, and which can be used sustainably, need to be enhanced by various levels of cultural, or other socioeconomic resilience (Connell, 2003), to reduce the likelihood that atoll communities will collapse in the face of climate or sea-level change (Barnett and Adger, 2003).

## Summary

Atolls represent some of the most remote and lowest-lying land on the planet. Each atoll comprises a reef rim that encloses a lagoon, which may be completed infilled on the smallest table reefs, but can be tens of meters deep on the largest. Lagoons vary considerably in the extent to which they are connected to the surrounding ocean. Carbonate sediment is produced by the growth of reef organisms, and it is swept by oceanic processes, particularly waves, toward the lagoon. On the rims of many atolls, sediment has accumulated as reef islands, which have been colonized first by salt-tolerant plants and in many cases by trees. A freshwater lens underlies the larger islands, and these have attracted human settlements often resulting in coconut plantations and the introduction of other plants and animals. Human impacts threaten the integrity of both terrestrial and marine ecosystems on atolls. Climate change appears likely to exacerbate many of these problems unless a more sustainable approach is adopted to augment the natural resilience of atoll ecosystems.

## AUVs (ROVs)

Noelle J. Relles, Mark R. Patterson  
 College of William & Mary, Gloucester Point, VA, USA

## Synonyms

UUVs, Unmanned underwater vehicles

## Definitions

*AUVs*. Acronym for autonomous underwater vehicles – untethered underwater vehicles under control of an onboard computer.

*ROVs*. Acronym for remotely operated vehicles – tethered underwater vehicles under direct control of a human operator at the surface.

## Introduction

Remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs) are increasingly used in studies of deep and shallow coral reefs. As a general rule, AUVs are computer-controlled taxicabs for sensors, need to continuously maintain some degree of horizontal motion, and do not collect physical samples. ROVs are swimming video cameras under direct human control that can stop and hover, and bring back an object or water sample to the surface using a manipulator arm or other mechanical device. However, hybrid AUV/ROVs with combined attributes now exist for military and geophysical surveys (e.g., Saab Double Eagle Seaeye <http://www.seaeye.com/doubleeagle.html>) and deep ocean oceanography (e.g., WHOI Nereus, which reached the Challenger Deep, Marianas Trench in June 2009, <http://www.whoi.com/page.do?pid=10076>). Hybrid AUV designs are particularly well-suited for the demanding navigational environment of coral reef environments because of their increased maneuverability (Dunbabin et al., 2004).

AUVs and ROVs allow the collection of data that might not be otherwise obtainable (Dickey et al., 2008), or at a reduced risk, or cost, compared to other sampling methods such as a scuba diver, towed platform, or ship (Patterson and Relles, 2008). ROVs were initially developed by the defense and oil industries. Maturation of the technology coupled with decreases in vehicle cost led to their adoption as a viable research tool by marine scientists (Stewart and Auster, 1989). In the 1990s, the US National Oceanic and Atmospheric Administration (NOAA) began offering ROV access to scientists funded through its National Undersea Research Program (<http://explore.noaa.gov/>). AUV technology had an intense research and development phase during the 1990s funded largely by national defense agencies (Curtin et al., 1993; Kunzig, 1996), with commercial vehicles not widely available until around 2000. NOAA added AUV access beginning in 2005 (<http://uncw.edu/nurc/auv/glider/pressreleases.htm>). During the past decade, many academic and government institutions purchased commercial AUVs, or transitioned their in-house engineering development AUVs to working research platforms.

## ROV technology

ROVs range in mass from a few kilograms to several tons, with tethers a few hundred meters to full-ocean depth in length. All ROVs possess a video camera or high-frequency imaging sonar to allow the surface operator to drive the vehicle by visual feedback from the image transmitted over the tether. Maneuvering is provided by orthogonal thrusters that allow independent control of vertical and horizontal motion, including rotation around the ROV's vertical axis. ROVs are usually weighted to almost

neutral buoyancy, allowing them to hover. Most ROVs are supplied with power through the tether, although deep-water ROVs may carry battery power on the vehicle instead, and use the tether only for image transmission and other data telemetry. An example of an ROV is shown in Figure 1. Almost all ROVs possess a manipulator arm under control of the surface operator that allows for the collection of biological or geological specimens (Figure 2). ROVs with sufficient power and size can carry

**AUVs (ROVs), Figure 1** ROPOS ROV on deck during 2006 expedition to deep-water coral reef, Pacific coast, USA. Credit: NOAA, [http://oceanexplorer.noaa.gov/explorations/08lophelia/logs/sept29/media/falcon\\_rov\\_arm.html](http://oceanexplorer.noaa.gov/explorations/08lophelia/logs/sept29/media/falcon_rov_arm.html).

other payloads including conductivity, temperature, and depth (CTD), acoustic Doppler current profilers (ADCPs), sidescan and multibeam sonars, and more specialized payloads like plankton samplers (Kirkwood, 1998) and micro-electrodes for porewater studies (Luther et al., 1999).

ROVs are most often deployed from a surface ship, and operated a short lateral distance away from the ship. Deep-water deployments may require the surface ship to station-keep using dynamic positioning. Because tether management is a complex task, ROVs are best suited for exploring relatively small (hundreds of square meters), targeted areas of the seafloor, rather than conducting large-area surveys. Geopositioning of the ROV is provided by acoustic means (UltraShort BaseLine – USBL, or Short BaseLine – SBL) relative to the surface ship's position.

### AUV technology

AUVs are free-swimming robots that can gather data with enough spatial and/or temporal resolution to reduce data aliasing (ORION, 2004). Most are torpedo shaped to reduce drag, contrasted with the box-like shape of ROVs, where drag minimization makes little sense given the already high drag of the ROV's tether. AUVs range in length from 1.5 to 5.5 m, with weight in air 20–1,400 kg. AUVs are slightly positively buoyant or have drop weights to produce positive buoyancy at the end of the mission. This ensures the AUV will surface even if onboard control systems have failed. AUVs are battery powered; small AUVs can deploy for several hours, while large vehicles can swim for several days. Survey speeds are usually 1–2 m/s, chosen to maximize range for the onboard battery power. Depth ranges are comparable to ROVs, with many vehicles capable of surveying to continental shelf depths, with few capable of full-ocean depth.

AUVs are well suited to *Swathe Mapping* and large-area surveys. AUVs carry multiple payloads, allowing synoptic coverage; for example, an AUV may simultaneously image the seafloor while measuring water quality. In addition to the payloads listed above for ROVs, AUVs routinely carry fluorimeters, turbidity and turbulence sensors, magnetometers, and water quality sensors

(Hayes et al., 2007; Nicholson and Healey, 2008). AUV position underwater can be determined using acoustic positioning relative to a surface vessel or subsea transponders, or by dead reckoning using a Doppler velocity log to measure speed over the bottom and direction using a compass, or by inertial navigation whereby the accelerations and rotations of the AUV are measured and equations of motion solved. Some AUVs may blend information from several navigational methods to obtain the highest possible accuracy using a nonlinear predictor–corrector algorithm called a Kalman filter (overview of AUV navigation available at <http://www.ise.bc.ca/WADenavandpos.html>).

AUVs are either driven by a propeller (Figure 3), or in the case of gliders, through changes in buoyancy that generate lift on wings on the glider, allowing lateral movement through the water. Propeller-driven AUVs are favored for near-bottom surveys (Patterson et al., 2008); gliders are typically used offshore to investigate currents, water column productivity, or water mass structure (Perry et al., 2008).

Unlike ROVs, AUVs fly preprogrammed missions, often “mowing the lawn” to survey the seafloor or “yo-yoing” over a reef to measure water quality. However, the flight path can be dynamically altered by the AUV, to adaptively sample features of interest (Fiorelli et al., 2004). Communication with the AUV during the mission can occur via acoustic modem when submerged or via radio frequency (cell phone, WiFi, satellite) when the vehicle surfaces.

### Applications to coral reef science

ROVs have proved very useful in the investigation of deep sea/cold water reefs (*Cold-Water Coral Reefs*) dominated by *Lophelia* (Fosså et al., 2005) and bioherms (*Bioherms and Biostromes*) constructed by *Oculina* (Reed et al., 2005), with video inspections and subsequent specimen collections often discovering new species. ROVs have also provided observational evidence of fish abundance (Parrish, 2006; Stevenson et al., 2007) and invasive species distribution (Kahng and Grigg, 2005) on tropical coral reefs.

**AUVs (ROVs), Figure 3** Examples of AUVs that have surveyed coral reefs. (Left) Fetch1 AUV (Patterson and Sias, 1998; US Patent 5995882), Virginia Institute of Marine Science (VIMS). Credit: NOAA. (Right) Seabed AUV (Singh et al., 2004). Credit: NOAA.

**AUVs (ROVs), Figure 4** Dissolved oxygen mapped over a coral reef in *Florida Keys*, by the Fetch1 AUV, useful in the inference of *metabolism*, *calcification*, and *carbon production*. The unaliased data collected to produce this image could not have occurred without the fast temporal and spatial sampling provided by the AUV. Credit: VIMS.

AUVs have mapped currents and bathymetry of coral reefs over large areas in deep water (Grasmueck et al., 2006), and made detailed photomosaics in shallower water (Armstrong et al., 2006). The physical oceanography of tropical coral reefs has also been surveyed by AUVs, including currents (Fong and Jones, 2006), plume dispersion (Jones et al., 2008), and hydrography and bathymetry (Shcherbina et al., 2008). AUVs are also well-suited to collect water quality data (Figure 4). Because AUVs can move sensors rapidly over a reef, they can help address the problem of data aliasing; aliasing occurs when data are sampled too coarsely in space or time to provide an understanding of nature's dynamics.

ROVs and AUVs are well suited for collecting video and still imagery, allowing analysis of landscape level patterns on reefs through photomosaic construction (Lirman et al., 2007; Ludvigsen et al., 2007). Mosaics of photos, side scan sonar, and multibeam sonar gathered by AUV or ROV are managed in a *Geographical Information System (GIS)*, providing reef scientists a useful tool for environmental monitoring, including assessment of the efficacy of marine protected areas (Patterson and Relles, 2008).

## Summary

Underwater robots such as AUVs and ROVs can gather data from reef systems over depth ranges, and at time and frequency scales, that cannot be obtained easily using other sampling techniques. Both technologies can serve as taxicabs for sensors and imaging systems, with AUVs well suited for large-area surveys, and ROVs suited for sample retrieval and video inspection of more limited areas.

## BACK-STEPPING

---

Paul Blanchon  
National Autonomous University of Mexico, Cancun,  
Mexico

### Synonyms

Transgressive reef

### Definition

Shallow-reef systems back-step to keep up with rapid relative sea-level rise. Back-stepping involves the demise of shallow-reef development at one site, and its relocation to another site further inshore and up-shelf. It is common during the onlap or retrogradation of tropical carbonate systems in transgressive systems tracts, and typical of glacial terminations during the Quaternary Ice Age.

### Introduction

Reef back-stepping has been widely recognized from the geological record where it is almost universally interpreted as a result of rapid rise in relative sea level (Smith and Stearn 1987; Kaufman and Meyers 1988; Ross 1992; Becker et al., 1993; Wendte and Uyeno 2005). Yet ironically, there has been considerable argument over its existence and significance in late Pleistocene and Holocene reefs. This largely stems from early assumptions that healthy reefs could accrete faster than the average rate of glacio-eustatic sea-level rise (Adey et al., 1978; Schlager 1981). Reef drowning in the strictest sense was therefore considered uncommon and only ‘incipient drowning’, where shallow reefs were initially submerged but subsequently recovered when the rise rate declined, was considered likely (Kendall and Schlager 1981). According to this early view, complete drowning of healthy reefs by

submerging them below the euphotic zone (~100 m) required exceptional circumstances: either a combination of regional subsidence and pulsed sea-level rise which removed the reef from the low-stand euphotic zone, or more local environmental factors to suppress the accretion potential of reefs and make them susceptible to drowning (Adey 1978; Kinsey and Davies 1979; Neumann and Macintyre 1985; Hallock and Schlager 1986; Vogt 1989; Hubbard et al., 1997).

Given the impact of global environmental deterioration on modern reefs, particularly those resulting from greenhouse gas emissions, it is important to clarify arguments concerning the cause of reef demise and back-stepping. This is because the processes postulated to have caused reef demise and back-stepping in the past are very similar to ones that have been identified as threatening reefs in the future. In this light, the investigation of reef back-stepping in the recent past is taking on a new sense of urgency.

### Reef back-stepping in stable terranes

The discovery of back-stepping in Quaternary reefs occurred when Fairbanks (1989) drilled submerged, postglacial reef terraces off the south coast of Barbados. His cores showed three back-stepping reefs containing thick monospecific sequences of the reef-crest coral *Acropora palmata*, which has a depth-restricted habitat range of ~5 m (Figure 1). By dating this reef-crest coral, he identified two rapid rises in postglacial sea level termed meltwater pulse (Mwp) 1a and 1b, but never analyzed the stratigraphy or recognized the significance of reef back-stepping *per se*. That recognition was made by Blanchon and Shaw (1995), who used elevation differences between the *A. palmata* sequences, and their transition into succeeding units, to constrain the rate and magnitude of those rapid-rise events. By including evidence from other submerged reef crests in the Caribbean, they also identified a rapid rise (Mwp-1c) in the early Holocene which caused a third reef back-stepping

**Back-Stepping, Figure 1** Caribbean three-step model of postglacial sea-level rise and the back-stepping reef-core stratigraphy. Reconstruction of sea level older than 8 ka uses uplift-corrected elevation and thickness of back-stepping *A. palmata* reef-crest sequences from Barbados, and precise  $^{230}\text{Th}$  ages from corals in those sequences (Fairbanks 1989; Blanchon and Shaw 1995; Peltier and Fairbanks 2006). Reconstruction of sea level younger than 8 ka is from back-stepping stratigraphy and calibrated radiocarbon-ages of relict and active Holocene reefs in tectonically stable areas of the Caribbean (Blanchon et al., 2002; Toscano and Macintyre 2003). The position of mean sea level is identified from coral age/elevation data that falls within a 5 m envelope (shaded), which represents the 0–5 m reef-crest habitat depth zone where *A. palmata* forms a monospecific assemblage mixed with clasts. Outliers from this envelope are a result of either upslope transport during storms, or from deeper habitat ranges of non reef-crest corals. Correction for continuous uplift of Barbados is assumed to be 0.34 mm/year but is ignored in order to quantify the rate and magnitude of sea-level jumps that caused episodes of reef-crest drowning and back-stepping.

event that led to the establishment of modern Caribbean reefs (Blanchon et al., 2002).

The discovery of reef back-stepping and rapid sea-level jumps in the Caribbean led others to look for similar events in other regions. Two cores recovered from the reef crest around Tahiti by Bard et al., (1996) found that the modern reef initiated there immediately following

Mwp-1a, much earlier than in the Caribbean, and then kept pace with sea-level rise (Figure 2). The lack of evidence of reef back-stepping during Mwp-1b and 1c led Montaggioni et al., (1997) to question the magnitude and/or existence of these events. However, the keep-up interpretation of the Tahiti cores was contested by Blanchon (1998) who argued that Indo-Pacific reefs might

**Back-Stepping, Figure 2** Tahitian reef-core stratigraphy and age-elevation data, compared to the Caribbean postglacial sea-level curve. Core stratigraphy shows a single episode of reef-crest back-stepping following Mwp-1a (P-core stratigraphy from Montaggioni et al. [1997] and Cabioch et al. [1999], ages from Bard et al. [1996]; Tiarei cores interpreted from data in Camoin et al. [2007]). Note that facies sequence in the late-Glacial cores from the Tiarei inner-ridge shows a biofacies inversion from robust-branching corals typical of high-energy environments to delicate-branching corals typical of low-energy settings. This inversion is typical of recolonization of drowned reefs by deeper-water coral assemblages. Tahitian and Huon Peninsula age-elevation data generally plots below Caribbean curve but shows a distinct pattern related to meltwater pulses 1a and 1b. The magnitude of the offset is largest following meltwater pulse events and gradually decreases thereafter. This pattern is consistent with submergence of Tahitian and Huon reefs of following sea-level jumps and gradual catch-up of the reef-surface with sea level. For the first two meltwater pulses, it can be seen that the offset is  $>10$  m and coincides with a change of biofacies. The offset related to the 8 ka jump however is  $<10$  m and coincides with a minor biofacies change in only one core, P6.

be relatively insensitive to rapid sea-level jumps because their assemblage of reef-crest corals had a larger depth range (10 m) and were more diverse and difficult to identify in core. This is supported by quantitative analyses of coral assemblages on the adjacent island of Moorea by Bouchon (1985) who found that the shallow crest assemblage of robust-branching corals extended down

the reef-front slope to  $\sim 10$  m. As a result, Blanchon (1998) suggested that back-stepping may not have been recorded because the magnitude of sea-level jumps during Mwp-1b and 1c was not sufficient to displace the Tahitian reef-crest assemblage out of its 10 m habitat zone, and the reefs rapidly rebuilt to sea level without registering a significant facies change in the cores.

Later coring on the Tahitian reef crest, however, showed systematic changes in coral assemblages which corresponded to the timing of Mwp-1b (Cabioch et al., 1999). Following Mwp-1a, the base of the sequence started in lower-reef-front slope assemblages (>10 m) but shallowed into upper-slope assemblages (<10 m) shortly before Mwp-1b. Following that rise event, assemblages reverted to lower slope as waters deepened, but quickly shallowed thereafter, and showed little or no subsequent changes related to Mwp-1c (Figure 2). In other words, the reef crest recovered following the first two meltwater pulses but did not register the last.

Despite the lack of clear facies changes registered at Tahiti during the 8 ka meltwater pulse, further evidence of reef demise and back-stepping has since been reported from several other areas around this time. Off the north coast of St. Croix, Hubbard et al. (2005) recovered core sequences from the interval of modern reef initiation, and found that *A. palmata* reef-crest assemblages had developed at 12 m by 7.7 ka (Figure 1). The comparison of this initiation age, with the terminal age of an early Holocene reef crest off the southwest coast (Adey et al., 1978), shows that reef back-stepping started at ~8 ka at a depth of ~21 m and was complete by 7.7 ka at 12 m. Although the precise age and depth of the early Holocene reef crest are uncertain due to the lack of core coverage, heavy encrustation of the cored *A. palmata* by coralline algae indicates that the reef-crest position could be no shallower than 18 m (cf. Steneck and Adey 1976). In other words, these data indicate St. Croix's reef-crest back-stepped 4–7 m in 300 years or less.

Similar evidence of rapid back-stepping has also recently been confirmed from southeast Florida, where Banks et al., (2007) reported coral ages from a single core and submarine grounding site (USS Memphis in 1993). These data indicate that a reef-crest facies, consisting of in-place *A. palmata*, initiated on the inner shelf 7.4 ka ago at 10 m below sea level (see inner reef-tract in Figure 3). Comparing the initiation age of this shallow reef with the demise of a deeper, early Holocene reef crest exposed in a sewage-outfall trench a further 3 km offshore (Lighty et al., 1978), shows that reef back-stepping had started by ~8 ka at a depth of ~17 m and was complete by 7.4 ka at 10 m (see outer reef-tract in Figure 3). These data therefore indicate that southeast Florida reef crests also back-stepped 4–9 m in ~450 years.

In addition to the Holocene and deglacial events, back-stepping has also been documented during the last interglacial highstand (MIS-5e) when sea level was as much as 6 m higher than present. Along the Red Sea coast of Eritrea, for example, an uplifted and tilted LIG reef sequence near Abdur clearly shows two superimposed stages of shallow-reef development (Bruggemann et al., 2004). The lagoon and patch-reef section of the lower reef unit is truncated by an intermittent marine-erosion surface and directly overlain by a 3 m crest and reef-front section of the upper-reef unit. This implies that reef-crest development back-stepped over an existing reef lagoon. But given the neotectonic

setting of this site, the possibility that co-seismic uplift produced reef back-stepping cannot be discounted.

A clearer example of back-stepping has recently been described from the northeast Yucatan by Blanchon et al., (2009) and Blanchon (2010). Two superimposed fossil reef units were documented. A lower patch-reef complex and adjacent crest unit at +3 m is overlain by a second reef unit with a crest at +6 m. Reliable radiometric ages confirmed both units were of last interglacial age but could not differentiate between them, mainly due to subtle diagenetic alteration of corals in the lower unit. However, the relative-age relations between the two units were clear. The framework of the upper-reef unit was infiltrated by shelly beach-gravel as sea level fell at end of the interglacial, but infiltration of lower reef was prevented by cap of crustose coralline algae. This infiltration pattern shows that the upper reef was younger and must have been alive shortly before sea level fell, and that the lower-reef was older and was dead when sea level fell. Areas of continuous accretion between the lagoonal patch reefs of the lower unit and reef crest and back-reef of the upper unit, however, require that the demise of the lower-reef was ecologically synchronous with initiation of the upper-reef tract. In other words, back-stepping took place on an ecological timescale. The relative differences between the elevations of the reef crests and flats in the two reef units, and the presence of 1.5-m tall colonies at the base of the upper-crest unit, indicate that this back-stepping was a result of a 2–3 m sea-level jump at the end of the last interglacial (Blanchon et al., 2009).

### Reef back-stepping in subsiding terranes

As suggested by Schlager (1981), the combination of subsidence and pulsed glacio-eustatic sea-level rise provides an ideal mechanism to trigger reef back-stepping. A good example has been described from the Huon Gulf, Papua New Guinea, where rapid and oblique convergence of the Australian and West Pacific plates, and intervening microplates, has produced a foreland basin with high rates of vertical displacement across its collisional axis (e.g., 12 mm/year; Abers and McCaffrey 1994). Flexure of the basin's cratonic margin has caused submergence and onlap during the last ~450 kyr and produced as many as 14 back-stepping platforms, with 7 confirmed as reefal in origin but with only 1 returning a reliable radiometric age (Galewsky et al., 1996; Webster et al., 2004a, b). Coral fragments from the base of platform PII recorded an age of ~60 ka, but there was no direct evidence for it being reefal in origin (Webster et al., 2004a). A single age from the talus of platform PXII, that is clearly reefal in origin, indicates that it was likely drowned by a major deglacial sea-level rise associated with the transition from MIS-10 to 9 (Galewsky et al., 1996; Webster et al., 2004b). However, the number of confirmed reefal platforms clearly exceeds the number of major deglaciations, and indicates that interstadial sea-level-rise events may also be responsible for platform drowning (Webster et al., 2009).

**Back-Stepping, Figure 3** Exposures in back-stepping relict breakwater reefs from Southeast Florida, and their implications for the rate and magnitude of Holocene sea-level rise. *Upper inset* shows morphology and facies of the outer relict-reef (Lighty et al., 1978), and below, an age–depth plot of *A. palmata* samples from three vertical transects (VT) shown on inset (calendar age and depth of samples reported by Toscano and Macintyre [2003]). Calendar ages in **bold** show timing of outer relict-reef demise at ~8.0 ka. *Lower inset* shows morphology and facies of the inner relict-reef depth (Banks et al. (2007), and above, an age–depth plot of *A. palmata* samples from a core at –6.8 m and an exposure 8 km further south made during the USS Memphis grounding. Calendar ages in **bold** show that initiation of inner relict-reef was ~7.4 ka. As such, these age–depth data show that reef-crest corals died off 8.0 ka ago and back-stepped 6 m vertically upslope in only 580 years, initiating a new phase of reef-crest development by 7.42 ka. This rapid back-stepping of reef crests could only happen if there was a 6 m jump in Holocene sea level. Below, LiDAR digital depth model showing positions of relict reef and coastal tracts sampled in exposures described in upper figure (Courtesy of Brian Walker and Bernhard Riegl, Nova Southeastern University).

Another good example of reef back-stepping in a rapidly subsiding terrane has been reported from Hawaii (Webster et al., 2004a, 2007). There, average long-term subsidence associated with volcanic loading of the lithosphere has been measured at 2.7 mm/year over the last ~500 kyr (Sharp and Renne 2006). This submergence coupled with glacio-eustatic sea-level change has produced 12 back-stepping linear ridges, of which 3 have been confirmed as reefal in origin and have radiometric ages (H7, 392 kyr; H2, 136 kyr; H1, 14.7 kyr; Webster et al., 2009). The oldest of these ridges (H7) returned U-series ages of 392–377 ka from corals at the base of the sequence. But this sequence also showed evidence of erosional breaks indicating the ridge may, in fact, be a composite unit consisting of several superimposed episodes of reef development (Webster et al., 2009). This preliminary evidence of multicyclic ridge development is also consistent with simulated reef development during the last two glacio-eustatic sea-level cycles (Webster et al., 2007).

The youngest of the Hawaiian ridges (H1) is a composite feature, consisting of three closely-spaced ridges between 150 and 105 m water depth. The deepest ridge has been investigated by ROV and samples from in-situ corals collected from the reef crest, returned ages of 15.8–14.7 kyr indicating that it drowned following Mwp-1a (Webster et al., 2004c). However, it is unknown if these ridges consist of single reefs formed during a single sea-level position or multicyclic sequences formed during more than one sea-level position.

### Cause of reef back-stepping

In both stable and subsiding terranes, the above evidence indicates that the proximate cause of reef drowning and back-stepping is rapid sea-level rise, particularly jumps in sea level caused by pulses in meltwater and iceberg discharge during deglaciation (Blanchon and Shaw 1995; Webster et al., 2004c). Direct measurement of the rise rates during these jumps clearly falsifies early assumptions that reefs can easily outpace sea-level rise, and therefore largely negates the paradox of reef drowning (Schlager 1981). Indeed, sea-level rise rates during these jumps exceed the accretion potential of modern and late Pleistocene reefs by as much as six times.

In addition to the rise rate, however, the magnitude of the jump is also critical for the drowning and back-stepping response of reefs. Evidence indicates that the ~15 m sea-level jump during Mwp-1a produced an ubiquitous back-stepping response from late Glacial reefs at all sites investigated. Cored reef sequences from the oceanic islands of Tahiti and Barbados both show that the position of shallow-reef development switched to an upslope location in 500 years or less. On Barbados, *A. palmata*-dominated crests moved upslope between 11 and 16 m in <450 years (although that duration could be significantly reduced by dating the base of the reef-crest sequence in RGF-12 in Figure 1). Whereas on Tahiti, new drilling on

the fore-reef slopes during IODP-310 has identified drowned reefs related to the back-stepping following Mwp-1a (Camoïn et al., 2007), and indicates that reef relocation started at 14.6 and was complete by at least 14 ka (although the precise timing and magnitude of this back-stepping remains to be reported) (Figure 2). The isolated oceanic nature of these two islands means that this back-stepping event took place in healthy reef systems that were largely unaffected by conditions that could suppress their accretion potential and make them more susceptible to drowning (such as rapid flooding of extensive continental shelves). As a consequence, their back-stepping provides clear support for the singular role of large-magnitude jumps in sea level. It is likely that jumps of this magnitude submerged reefs below an optimal accretion window and re-established this window far enough upslope that the original communities were unable to recover due to rapid deterioration in light levels and/or sediment flux. This is supported by core sequences from both islands, which show an immediate switch to deeper-water communities following Mwp-1a and indicate that only 10–15 m of subsequent deep-reef accretion took place. In the case of Barbados, that accretion had ceased completely by ~12 ka when sea level had submerged the drowned reef by ~30 m (see RGF-15 in Figure 1, but note that accretion in RGF-9 may have been supplemented by downslope sedimentation from early reef growth at RGF-12).

The response of reefs to the subsequent smaller magnitude sea-level jumps, however, was not consistent between oceanic reef provinces. In the Caribbean, for example, Mwp-1b did trigger reef back-stepping. Barbados cores show that a reef-crest sequence at 50 m in RGF-12 was abruptly replaced by a deeper *A. cervicornis* unit, and shifted 5–10 m upslope in <314 years in RGF-8 (Figure 1). But at Tahiti, no evidence of back-stepping has been found in cores through the modern reef crest, where the sequence simply shows a switch from robust-branching to tabular-branching assemblages at ~50 m. It should be noted that this lack of evidence does not mean that back-stepping did not occur, just that it is undocumented. It might be that the islands fringing reefs, which have largely been ignored, initiated at this time.

A similar lack of consistency also resulted from the final sea-level jump, Mwp-1c, starting at 8 ka. In the Caribbean, many areas including Barbados show *A. palmata* reefs that established at the beginning Holocene had died off by ~8 kyr, just as modern reef structures were initiating (Figure 1; Blanchon et al., 2002). Initial explanations of this early Holocene die-off were formulated before there were adequate data on the age of modern reef initiation, and so the close timing between the two generally went unappreciated. Subsequently, however, the age of modern reef initiation has been reported from many areas including, more recently, southeast Florida and St. Croix where it occurred between 7.8 and 7.6 ka at depths of 10–12 m (Figures 1 and 3). Drowned reefs that died off during the 8 ka jump have also been reported from several areas, most recently Grand Caymen and the

Gulf of Carpentaria where their reef crests occurred at a depth of ~20 m (Blanchon et al., 2002; Harris et al., 2008). So, between 8 and 7.6 ka reef-crest sequences throughout the Caribbean, and perhaps other areas, back-stepped upslope between 4 and 8 m (Figure 1 and 3). Yet despite all this activity in the Caribbean and other seas, reef sequences in Tahiti apparently show no evidence of back-stepping at 8 ka, and don't even register a response in the facies sequence (Figure 2).

The key question then is why should Tahitian reefs, and possibly Indo-Pacific reefs in general, be more resilient to rapid sea-level jumps than those in the Caribbean? An obvious possibility is that the greater diversity and depth range of Indo-Pacific reef-crest assemblages provides a broader insurance coverage against the environmental changes wrought by rapid sea-level jumps. In Caribbean reefs, with their shallow and almost monoculture-like crest assemblages, such rapid changes must be difficult to insure against and they therefore have a much greater impact. A clear example of this vulnerability is illustrated by the back-stepping event during the last interglacial from the northeast Yucatan (Blanchon et al., 2009). In this case, even a small 3 m jump led to an unfavorable sedimentation regime that resulted in the severe restriction of reef development along the northeast coast of the Peninsula and apparently to extirpation of reefs in the Bahamas and other low gradient coasts (perhaps even as far a-field as western Australia).

The ongoing widespread decline of Caribbean reefs, however, is perhaps the strongest evidence of this vulnerability. While Indo-Pacific reefs show increasing signs of being resilient to rapid environmental changes (Adjeroud et al., 2009; Diaz-Pulido et al., 2009), coral cover in the Caribbean continues its steep decline (Gardner et al., 2005). The cause of this dramatic degeneration is widely debated, but recent analyses indicate that chronic human disturbance via overfishing and nutrient input, coupled with disease outbreaks, has synergistically impaired the regenerative potential of reefs following major disturbance events, such as hurricanes or thermal mass bleaching induced by global warming (Gardner et al., 2005; Mora 2008; Mumby and Steneck 2008; Raymundo et al., 2009). Add to this the increasingly dire predictions of future rapid sea-level rise, and what we could be witnessing in the Caribbean is the initial stages of the next episode of reef demise and back-stepping.

Bafflestone is a modification of Embry and Klovan (1971) to the Dunham (1962) Boundstone limestone type. It recognizes that the framework organisms acted as baffles to sedimentation.

### Definition

“Bahamas” denotes the Bahamas Archipelago of 700 islands and approximately 2,400 cays and rocks that stretches from 27°36′ to 19°52′N latitude and from 79°05′ to 68°42′W longitude, a distance of about 1,300 km (Figure 1). That includes the Caicos and Turks Islands as well as Mouchoir, Silver, and Navidad Banks that are geographically, geologically, and ecologically part of the Bahamas, although separate entities politically. The land area of the Bahamas Commonwealth is 13,900 km<sup>2</sup>, home to some 306,000 people on 30 of the islands and host to 4.6 million tourists annually (Government of the Bahamas). By far the largest part of the Bahamas, some 155,000 km<sup>2</sup>, lies beneath the sea (Newell, 1955). Of interest here are the vast shallow (<20 m) banks, the Great Bahama Bank (GBB), the Little Bahama Bank (LBB), and the smaller banks extending far to the southeast, encompassing about

125,000 km<sup>2</sup> (Bergman et al., 2010). The shallow banks from Caicos to Navidad Bank add another 10,200 km<sup>2</sup>. These banks are the largest area of coral-reef development in the Western Hemisphere. The reefs were an important resource for the indigenous Lucayans and were noted early by European explorers, beginning with C. Columbus.

### Introduction

The Bahama Banks, surrounded by deep water on all sides, provide excellent analogs for the numerous isolated carbonate platforms in the geological record. Sedimentologic studies in the Bahamas have been extensive, for example, by Black (1933), Smith (1940), Illing (1954), Cloud (1962), Purdy (1963), Ball (1967), Shinn et al. (1969), Hardie (1977), Harris (1979), Hine et al. (1981), Droxler and Schlager (1985), and numerous others. Basically, the broad platform interiors are blanketed by pellet and grapestone (aggregate grains, typically of pellets) sand with increasing mud content in the lee of larger islands on the windward margins (Traverse and Ginsburg, 1966; Enos, 1974). The windward sides of the islands are the favored sites of reefs and skeletal sands. Where island

and bank configuration focus tidal currents, ooid shoals are formed.

Tectonic and stratigraphic studies have established that up to 10 km of largely shallow-water carbonates, Jurassic to Holocene in age, overlie rifted Jurassic transitional crust in the NW Bahamas and oceanic crust SE of Tongue of the Ocean (TOTO, Sheridan et al., 1988), although others have argued for African continental crust (Mullins and Lynts, 1977). A carbonate “megabank” developed in the Early Cretaceous that may have included the Bahamas, Florida, and Yucatan (Austin and Schlager, 1988). This bank was fragmented into smaller platforms separated by subsiding blocks in the mid-Cretaceous. The southern part was further fragmented during collision with Cuba in Late Cretaceous–Middle Eocene (Masafello and Eberli, 1999). Seismic stratigraphy shows that leeward lateral accretion of sediment derived from the bank tops has filled such depressions, merging platform fragments during the Cenozoic to form the GBB (Eberli and Ginsburg, 1987, 1989; Masafello and Eberli, 1999). Deep channels (Straits of Florida, Santaren Channel, Old Bahamas Channel, Providence Channels) and reentrants (TOTO, Exuma Sound) remain. These dissect the banks and isolate them from terrigenous input except for wind-blown dust that reddens the soils.

Coral reefs were common around the margins of the Bahama Banks at least as far back as the Pliocene (Beach and Ginsburg, 1980). Pleistocene reefs are exposed on most of the major islands (Cant, 1977), some extending to 5 m above present sea level (Hearty, 1998). Lithified Pleistocene eolianite dune ridges form the bulk of the Bahaman islands, however, reaching 63-m elevation on Cat Island (Government of the Bahamas). Subtidal Pleistocene deposits extend up to 6 m above sea level on the large islands. Multiple Holocene beach-accretion ridges, anchored by Pleistocene buttresses, form many low-lying areas. Origins from dunes, beaches, and reefs dictate that the largest islands (Andros, Eleuthera, Great Abaco) and highest (Cat Island) lie at the eastern margins of the banks, where tides, trade winds, and wave fetch maximize skeletal sediment production (Ball, 1967).

Most islands have multiple nested rows of Pleistocene dunes, generally younging toward the windward margin. This is well illustrated on New Providence and adjacent islands where six prominent ridges are visible on topographic maps (Hearty and Kindler, 1997). Strings of small cays formed by eroded dunes near the shelf break are common around the Bahamas, even on the shallower leeward margins, e.g., from Bimini south beyond Cat Cays. Similarly, the eroded remnants of dunes, beaches, and reefs dominate the submarine topography at the margins of the Bahama Banks. This combination of linear, arcuate, and spur-and-grove ridges are the substrate for modern reef growth, as well as vast areas of coral-encrusted hard grounds.

Environmental parameters that impact the reefs most directly include climate and hydrology. Bahaman climate ranges from humid subtropical with dry winters in the

NW (18–28°C monthly average temperature, 73–79% humidity, 135.5 cm annual rainfall on Grand Bahama Island) to subarid tropical in the SE (25–34°C, 18–25%, 60.4 cm/year, Caicos). About half of the area lies within the tropics; the Tropic of Cancer bisects Little Exuma Island. Sea-surface temperatures range from 21.7 to 28.3°C annually on the Andros lobe of GBB (Cloud, 1962) compared to 26–29°C on Caicos Bank.

The Bahamas lie in the northeasterly trade winds belt, but continental low pressures over North America produce predominately southeasterly winds during the warmer months (Smith, 1940). Continental cold fronts occasionally impinge on the northwestern Bahamas in winter, producing strong NW winds and cooling the bank water with air temperatures down to 3°C. Hurricanes struck the Bahamas–Turks area 121 times from 1901 to 1963 (compiled from Cry, 1965), an average of two per year. Twenty-one of these storms passed directly over Andros Island. The damage to reefs from wave pressure and sediment abrasion can be severe, although it is quite variable, depending on storm intensity, direction, duration, and frequency.

The Bahamas are bathed by the north equatorial current that bifurcates to produce currents of 30–42 cm/s along the eastern islands and 46 cm/s in Old Bahama Channel to the south (Carew and Mylroie, 1997). The Gulf Stream skirts the western Bahamas with velocities up to 200 cm/s (Bergman et al., 2010). The range of semidiurnal tides is about 1 m at the platform margins everywhere in Bahamas. Resonance in the deep embayments, such as TOTO, can amplify the tides and produce strong currents at the margins, generating ooid shoals instead of reefs (Ball, 1967). Water at the bank margins has normal marine salinities, about 36 ppt, but sluggish circulation on the larger banks, where residence time can reach 240 days, produces salinities reaching 43 ppt in the hotter months (Broecker and Takahashi, 1966).

### Reef distribution

Bank/barrier reefs in the Bahamas occur almost exclusively on the windward (eastern) sides of banks. They are best developed on margins facing the open Atlantic swell (Rankey et al., 2009) and where large islands provide protection from the flux of bank-top water. The fluctuations of bank water in temperature, salinity, nutrients, and turbidity are detrimental to most corals, although patch reefs thrive on some areas of the banks. Lee margins, where wave energy is minimal and wind-driven flux of bank water is maximum, have few reefs that are small and deeper.

Reefs occur intermittently for 160 km along the north-east-facing margins of LBB, from beyond Walker’s Cay at the north to Elbow Cay at the middle of Great Abaco Island. The narrow, steeply sloping shelf further south, which faces ESE, has few reefs (Feingold et al., 2003; Rankey et al., 2009). Reefs on the LBB extend 220 km further north than Florida reefs despite the partiality of the Gulf Stream to Florida. Coral cover averaged only 14%

in the Abaco reefs, which contain 36 scleractinian species (Feingold et al., 2003).

The Andros reef tract bordering TOTO on GBB is 217 km long, a close second to the more continuous Belize reef tract, longest in the Atlantic. Coral cover in 1997–1998 was  $38 \pm 17\%$  for reef crests ( $<3.5$  m), the highest in the Atlantic, and  $25 \pm 14\%$  for fore-reef transects (5.5–12.5 m; Kramer, 2003). Disease and extensive bleaching events (stress-induced loss of symbiotic zooxanthellae) in 1998 and 2005 reduced cover to  $<10\%$  on some fore reefs (Kramer, 2008). Reefs in the Berry Islands are limited to small fringing reefs and near-shore patch reefs, despite the very exposed setting (Figure 1).

The Exuma Islands' setting is similar to Andros, facing deep water of Exuma Sound. However, bank/barrier reefs are virtually absent, apparently because of the small size of the islands and the many tidal channels into the bank interior. Corals, gorgonians, and sponges colonize hard substrates in tidal channels and on the narrow shelf windward of the islands (Chiappone et al., 1997a). Patch reefs are abundant in the platform interior (unpublished data; Taft et al., 1968).

At the NE corner of GBB, Eleuthera Island, 135 km long, faces the abyssal open Atlantic Ocean. Flourishing shallow reefs that fulfilled expectations of this setting in 1990 were reduced to algal-dominated shadows by 2000 and have not recovered (Craig Dahlgren, pers. commun.). Reef development was continuous along the east-facing southern half of the island; gaps appeared further north. Pigmented skeletal fragments of the abundant encrusting foraminifer *Homotrema rubrum* produce the famous pink beaches of Eleuthera.

Cat Island, 85 km long and facing NE into the open Atlantic, has well-developed reefs, except where oceanic waves impinge directly on the sea cliffs. Long Island, comparable in size and setting at the eastern extremity of GBB, has well-developed bank/barrier reefs and patch reefs on the narrow shelf along the north three-quarters of the windward margin. Imagery is poor further south, but lack of breakers suggests lack of barrier reefs.

Of the numerous isolated banks, only two have been studied in any detail, the small San Salvador bank ( $\sim 150$  km<sup>2</sup>; Peckol et al., 2003) and the largest, Caicos platform (7,800 km<sup>2</sup>; Wanless and Dravis, 1989; Sullivan et al., 1994; Chiappone et al., 1996; Rankey et al., 2009). These studies as well as anecdotal accounts and imagery analysis (Google Earth with widely variable resolution) show that all of the banks have bank/barrier reefs and patch reefs where substantial shelf exists. Reefs are best developed on NE-facing margins, which are perpendicular to the predominant wave direction in the adjacent North Atlantic. However, shallow reefs are present on all but the westernmost, leeward margins. Even here are a few smaller, deeper reefs that have not aggraded to sea level (Rankey et al., 2009).

Patch reefs are rare on much of the Andros lobe of GBB and in the Bight of Eleuthera, probably because of the soft, muddy substrates and elevated salinities. In contrast, on the less restricted Exuma lobe and southeastern GBB, where hard substrates are plentiful, patch reefs abound, ranging in size from a few coral heads to reef clusters 1,200 m in length with areas over 1 km<sup>2</sup>. Density of patch reefs visible on satellite imagery ( $>$ about 10 m diameter) on the Exuma lobe is 25 per km<sup>2</sup> (unpublished data).

**Bahamas, Figure 2** Schematic profile of Bahaman platform-margin slopes. No vertical exaggeration! From Grammer and Ginsburg (1992).

Flourishing reefs attain relief of 4 m or more. At the margins of platforms, large and small patch reefs are common on the narrow shelves between bank/barrier reefs and islands.

The Bahamas even boast one atoll, Hogsty Reef, north of Great Inagua (Milliman, 1967).

**Bahamas, Figure 3** *Acropora palmata*, aka moosehorn or elkhorn coral, the reef-crest dominant. Exumas National Park, Cambridge Cay. Courtesy of Tim Taylor.

Stromatolites, layered mounds of varied shapes up to 2.5 m high composed of carbonate sand bound by microbial mats and lithified by marine carbonate cement, form transverse “reefs” or sediment dams in high-energy tidal channels (Dill et al., 1986). Similar structures also occur in a sandy embayment and intertidal beaches (Reid et al., 1995), but all 14 localities studied are in the Exuma Islands.

Deeper waters in the Bahamas host major coral growths, commonly called reefs, although few have significant constructional relief. A typical margin of a Bahaman platform has a shallow slope break at a barrier reef or the edge of the flat-topped bank. A narrow slope descends in a series of erosional and constructional terraces to a sharp slope break at –25 to –60 m, where a near-vertical “wall” plunges for about a 100 m (Figure 2; Grammer and Ginsburg, 1992). The wall is probably a Pleistocene sea cliff, buried at the base by cemented rubble from above. This configuration is obscured on many leeward margins by thick drifts of sediment washed off the bank tops. Rocky terraces at the top of the wall support thickets that include 69 types of sponges, 28 species of corals, 27 species of octocorals, and *Millepora alcicornis* (Bunt et al., 1981). The vertical wall, within the “mesophotic zone,” is covered by a profusion of sponges (Maldonado and Young, 1996) as well as corals and octocorals, which have not been studied. Sponges, which extend beyond depths of 500 m, include the light-shunning sclerosponges that secrete massive carbonate skeletons (Hartman, 1980).

#### Reef biota and zonation

The dominant frame builder of most shallow bank/barrier reefs of the Bahamas, as throughout the Caribbean, has been *Acropora palmata* (Figure 3). Despite marked decline over several decades, it constituted 62% of the corals ( $\geq 25$  cm) counted from reef crests of the Andros

**Bahamas, Figure 4** Relative abundance of stony corals ( $\geq 25$  cm diameter) in the Andros reef tract. (a) Reef crests (<3 m deep). (b) Fore reefs (8–12 m deep). From Kramer et al. (2003).

<sup>a</sup>After Chiappone et al. (1996, 1997a), Bunt et al. (1981); updates from J. C. Lang (pers. comm.)

Taxonomic names are consistent with Integrated Taxonomic Information System.

reef tract in 1998 (Kramer et al., 2003), although it is much reduced today. It was less dominant elsewhere: 35% in Turks and Caicos reefs (Riegl et al., 2003) and 13–18% at San Salvador (Peckol et al., 2003). Abaco reefs on LBB are low-relief structures dominated by *Porites astreoides*, *Diploria* spp., and *Millepora* spp. These northernmost reefs in the Atlantic, except for the Bermuda outlier, are apparently beyond the optimal range of acroporids. Arborescent *A. cervicornis* (staghorn coral) once formed vast thickets in many reefs, but they are largely a memory, victims of disease and destruction.

In shallow fore-reef and back-reef environments, massive heads of the *Montastraea annularis* species complex (MASC) are dominant. The complex encompasses three similar sympatric forms, considered valid species by Weil and Knowlton (1994), but overlapping morphologically in the Bahamas (Fukami et al., 2004). Prior studies treated *M. franksi* and *M. faveolata* as environmentally controlled variants of *M. annularis* (boulder coral) and some current work continues this practice. In the Andros fore reefs, 67% of the counts of corals  $\geq 25$  cm were MASC in 1988; 45% were *M. annularis* S.S. (Figure 4; Kramer et al., 2003). Given the robustness of MASC colonies, the spatial dominance would be even greater. *Montastraea* is less

dominant in other surveyed Bahaman reefs, including Abaco, although this is well within its geographic range.

Common accessory corals on all reefs include *Porites astreoides*, *P. porites*, *Agaricia* spp., and *Diploria* spp., and any of these may dominate on a specific reef. *Siderastrea siderea* is also nearly ubiquitous, but is more common in deeper and more sheltered settings. The hydrozoans, *Millepora alcicornis* and *M. complanata*, occur throughout the reefs with abundances as high as 20% (Abaco, Feingold et al., 2003). A complete list of observed Bahaman corals includes approximately 43 species (Table 1), comparable to the most diverse (and well studied) sites in the western Atlantic (Chiappone et al., 1996; Kramer, 2003).

Among patch reefs, MASC is dominant with varying abundances of *Diploria* spp., *Porites porites*, *P. astreoides*, and *Siderastrea siderea*. *Millepora alcicornis* is always

<sup>a</sup>After Chiappone et al. (1997b) and Bunt et al. (1981).

present, especially as encrusters on senescent patches. Patch-reef coral diversity is high, e.g., 26 species in the Exumas (Chiappone et al., 1997a), despite the absence of acroporids. Pante et al. (2008) reported a decline in coral cover from 13 to 3%, accompanied by extensive rubble production, on an Exuma patch reef between 1991 and 2004. MASC was the biggest loser, although it remained dominant, whereas *M. alcicornis* gained both in coverage and number of colonies.

Corals on the deeper terraces and the wall are also dominated by MASC (45% of coral cover) and *Siderastrea siderea* (20%) (Bunt et al., 1981). The 26 species reported include all of the forms abundant on the shallow reefs (Table 1), except the acrophobic acroporids.

Atlantic reefs contain many more octocorals and sponges (Figure 5) than Pacific reefs, which have much higher coral diversity. Thirty-five species of octocorals have been identified from the Bahamas (Table 2; Bunt et al., 1981; Chiappone et al., 1997b). Wiedenmayer (1980) recorded 84 species or forms of sponges from shallow rock and reef substrates. Curiously, the brightly colored, ubiquitous, and prodigious reef/rock borer, *Cliona*, was not among them. Of the 19 deep-water sponge genera mentioned anecdotally by Maldonado and Young (1996), 16 are not recorded from shallow water.

Crustose coralline algae, including *Lithophyllum congestum* and *Porolithon pachydermum*, are common in Bahaman reefs (Adey, 1978), constituting 30% of the total algal cover (Kramer, 2003). They construct cups and linear “algal ridges” on Great Inagua and the Plana Cays (east of Crooked–Acklins platform), although ridges are lacking further north (Adey, 1978). Arborescent *Jania*, *Amphiroa*, and *Neogoniolithon* contribute generously to

the sediment accumulation, if not to the mass of the reefs. Calcified green algae, notably *Halimeda opuntia*, are the major contributors to the skeletal sand around reefs because of their high production and disarticulation rates. Multitudes of fleshy macroalgae populate the reefs. They are considered a sign of declining reefs, as they can outcompete stony corals for space and light, especially since the catastrophic die-off of the algal-grazing urchin, *Diadema antillarum*, in 1983 (Kramer, 2003). Andros reef tract had the highest “macroalgal index” (relative abundance x colony height) reported from the Atlantic to 1999 (Kramer, 2003), although later surveys in the central and western Caribbean reported indices up to 40% higher (AGRRA database, <http://www.agrra.org>).

Reefs are the shelter, grazing range, home, or hunting grounds of many organisms. Prominent in the Bahamian reefs are multitudes of fish (Kramer, 2003), urchins, lobsters, shrimp, worms, bivalves, gastropods, bryozoans, anemones, and foraminifers. Particularly important in degrading the reefs into sediment are various bioeroders that include fungi, cyanobacteria, sponges, lithophagid and pholad bivalves, chitons, boring and rasping gastropods, sipunculid and polychaete worms, barnacles, boring and rasping echinoids, parrot fish, and many other grazing fish.

### Reef health

Worldwide decline of reefs, one of the most diverse of ecosystems, is causing grave concern and intensive research. A reef-health index based on 13 parameters including coral cover, mortality, and disease; macroalgal index; and fish populations was devised from the initial AGRRA survey of Atlantic reefs (Kramer, 2003). Andros had the worst health index of 17 Caribbean and Gulf sites

**Bahamas, Figure 6** *Porites*-dominated reef; the future of Bahaman reefs? Cochinis Bank, southeastern GBB (Courtesy of Tim Taylor).

compared and Abaco the third worst. Turks/Caicos ranked “average.” Coral bleaching, such as the worldwide event during El Niño conditions in 1998, and consequent diseases may be the most destructive agents. Since the survey, a new threat to the fish population, and perhaps the entire reef ecosystem, has arisen through the accidental introduction of the voraciously carnivorous lionfish, *Pterois volitans*, from the Indo-Pacific. Despite this gloomy picture, it seems possible that Bahaman reefs, now near the low-temperature limit, may benefit from global warming by shifting toward a more tropical ecology.

AGRRA surveys in the Bahamas, as elsewhere, show that recruitment rates of “brooder” corals such as *Porites* spp. and *Agaricia* spp. are much higher than those of broadcast spawners, including *Acropora* spp. and *Montastrea* spp., the former dominants on shallow and deep reefs, respectively (Kramer, 2003). If this portends a shift in reef populations, perhaps the words of Opdyke et al. (2007), “I have seen the future, and it is *Porites*,” are prophetic. Nevertheless, Bahaman reefs could remain productive and beautiful (Figure 6).

## Summary

The Bahama Banks and adjacent platforms, the largest area of coral-reef development in the Western Hemisphere, are excellent analogs for the isolated carbonate platforms in the rock record. Bank/barrier reefs line the windward margins of most platforms. Patch reefs are widely distributed across those platforms with more open circulation and hard substrates. Into this century *Montastrea annularis* “complex” dominated the fore reef and patch reefs; *Acropora palmata* the bank/barrier-reef crest. Octocorals, sponges, and calcareous algae are important and diverse components of Bahaman reefs.

## **BANKS ISLAND: FRASNIAN (LATE DEVONIAN) REEFS IN NORTHWESTERN ARCTIC CANADA**

Paul Copper

Laurentian University, Sudbury, ON, Canada

During the Frasnian (385.3–374.5 my), stromatoporoid sponge and coral reefs were restricted to about 5,000 km<sup>2</sup> of Banks Island (Thorsteinsson and Tozer, 1962). The

more than 2,000 km long preceding Middle Devonian barrier reef platform, extending westward from Greenland, lay buried in thick sands, silts, and muds. Banks Island reefs are remarkable for several reasons: (a) they were built up on the margins of an equatorial super delta, fringed by one of the oldest coastal lowland forests, whose margins harbored primitive-jawed placoderm fishes, and some of the first amphibians; (b) they flourished in the early and mid-Frasnian, prior to the Frasnian–Famennian global mass extinction events; (c) the reefs grew in four cycles,

**Banks Island: Frasnian (Late Devonian) Reefs In Northwestern Arctic Canada, Figure 1** Large patch reef, ca. 400 m diameter, B-level, Mercy Formation, located along the north banks of the lower Mercy River tract (NTS 88F/3, 578:176) facing reef B62.

**Banks Island: Frasnian (Late Devonian) Reefs In Northwestern Arctic Canada, Figure 2** The north end of Gyr Falcon Bluff close to the southern edge of Mercy Bay, Banks Island: the ca 60 m high bluff consists of two large C-level reefs that almost fused, a northern reef (visible) and a southern reef, hidden in the southern background in this helicopter view.

reflecting global eustatic sea level changes, probably related to glaciations in Brazil; and (d) the reefs reflected back-stepping events to the east during sea level highstands, and westward retreat at lowstands. The Frasnian is generally characterized by a lower diversity reef ecosystem than seen in the preceding Middle Devonian, with the Devonian reef ecosystem collapsing step-wise toward the end of the Frasnian Mass Extinctions (Copper, 2002) (Figures 1 and 2).

The Banks reef builders were dominated by exquisitely preserved stromatoporoid sponges as massive, platy forms meters thick, and in large domal forms that inhabited the open ocean, high energy fore-reef zone. In the back-reef lagoons, or off-reef deeper waters, stromatoporoids and corals grew as branching structures (Copper and Edinger, 2009). The corals and sponges probably had photosymbionts, as do many modern reef dwellers. The digitate stachyodid and slender matchstick-sized amphiporid

**Banks Island: Frasnian (Late Devonian) Reefs In Northwestern Arctic Canada, Figure 3** The carbonate platform levels B, C and D of the Frasnian Mercy Formation as seen from the air looking northwest along the East Mercy River branch. The B level reef is in the upper left background, and C-D levels in the foreground.

**Banks Island: Frasnian (Late Devonian) Reefs In Northwestern Arctic Canada, Figure 4** D-level upper 11A and 11B reefs in the Mercy Fm along the M'Clure River, northeast coast Banks Island: these reefs rest on top of siliciclastics and are buried by deltaic siliciclastics (NTS 88C/14, N74° 0.371', W117° 0.727').

stromatoporoids grew in upright bushes, usually on fine lime mud substrates that indicate sheltered environments.

The Banks reef tabulate and rugose corals were more diverse than the stromatoporoids, but volumetrically <30% of the reef mass, though some patch reefs were monospecific thamnoporid corals. The calcitic microstructure of Banks corals is commonly better preserved than modern day scleractinian corals. Solitary cup corals were very rare on Banks Island. In overall construction strategy, rugose corals were dendroid, phaceloid, cerioid, thamnasterioid, and aphroid forms, but lacked the meandroid ‘brain coral’ morphology of modern taxa. For the tabulate corals, dominant were the alveolitids (flat- to dish-shaped to cup-shaped, like the living lettuce coral *Agaricia*), coenitids (flat or branching), and thamnoporids (branching, almost identical to living *Porites porites*). The corals were more abundant as thickets, usually reef-flanking or biostromal, or as a lesser component within the fore-reef or reef flat. Unique for the Devonian, some corals and stromatoporoids grew on foundered tree trunks, the oldest known in the fossil record. Except for rare armored fragments and teeth, fishes were scarce in the Banks reef setting, as were shelly brachiopods, calcareous green and red algae.

Patch reefs ranged from a few meters in height and diameter to massive rounded to elongate mounds to a kilometer or more long and 30–50 m in composite height (Thorsteinsson and Tozer, 1962; Copper and Edinger, 2009) (Figure 4), found throughout the 220 m thick carbonate succession of the Mercy Bay Formation. Platform reefs, with a reef flat and slope up to ca. 30°, developed only at one Frasnian sea level highstand, and these were irregular in plan view, with scalloped edges possibly fringing delta lobes (Figure 3). Reefs generally initiated growth on coral debris.

## BANKS, JOSEPH (1743–1820)

Norman C. Duke  
University of Queensland, Brisbane, QLD, Australia

Banks, a founding father of natural science and co-founder of Australia, was born in London, Great Britain, on February 13, 1743, the only son of a wealthy landowner. He married Dorothea Hugesson on March 23, 1779. He

died in Isleworth, London, on June 19, 1820, aged 77. Banks devoted his entire adult life toward the advancement of science.

On his triumphant return from Captain Cook’s first great voyage in 1771, the young Banks was famously dubbed “The Botanic Macaroni” and “The great South Sea caterpillar.” Over the next 50 years, however, this satiric “caterpillar” was transformed into the “Bath Butterfly” by his royal investiture as Knight Commander of the Order of the Bath in 1795 (Figure 1). He was honored for his remarkable achievements in an era of enlightened human endeavor with his: knighthood (1781); membership of the Privy Council (1797); and his unmatched 4-decade term as President of the Royal Society (1778–1820). Banks galvanized the great scientific minds of his time, systematized natural history collection, and promoted foundation projects.

His early credentials were botanical collections (in the British Museum) from expeditions to: Labrador and Newfoundland (1766–1767); the southern ocean with Captain Cook (1768–1771); and Iceland and the New Hebrides (1772). Subsequently, he funded and encouraged others to gather and catalogue specimens of plants and animals throughout the world. Using his unofficial directorship of Kew Gardens in London to explore the economic and social benefits of plants, he created one of the world’s great public gardens.

Banks was a natural leader, a rare individual with no political leanings or ambitions. Though a favorite of

**Banks, Joseph (1743–1820), Figure 1** Sir Joseph Banks in full regalia as President of the Royal Society, by Thomas Phillips, 1808–1809.

King George III, he maintained a friendly correspondence with Benjamin Franklin in revolutionary America. He did not discriminate between British and foreign scientists. He helped maintain scientific relations with France during the French Revolution and the Napoleonic Wars. Banks was greatly respected by Carl Linnaeus, who devised the binomial naming system used today for all plants and animals. Banks applied the Linnaean method to his burgeoning museum collections. From 1772 to 1820, his collectors voyaged to Cape of Good Hope (Francis Masson, James Bowie); West Africa (Mungo Park); the East Indies (Mungo Park); South America (Allan Cunningham); India (Anton Hove); and Australia (David Burton, George Caley, Robert Brown, Allan Cunningham, and George Suttor). David Nelson went on Cook's third voyage (1776–1780) and with Bligh on the "Bounty" (1787–1788). Archibald Menzies collected for Vancouver's North American voyage (1791–1795).

It is not surprising that more than 80 plant species bear his name, including the renowned Proteaceous genus, *Banksia*. His patronage of municipal works and voyages of discovery have ensured that his name also dots maps of Britain, North America, the Pacific islands, and Australia. The latter, as New South Wales, was much influenced by his patronage. Banks was a leading authority and advisor to the British government. In 1779, he recommended Botany Bay for convict settlement. In 1780, he organized surveys by Matthew Flinders, who mapped and named Australia for the first time. Banks communicated with each of the four early governors. Practically everyone who had an interest in early Australia consulted Sir Joseph Banks.

**On risk taking.** . . 1806 (aged 63). Writing to WJ Hooker, then a promising young student who was reluctant to travel. "I was about twenty-three when I began my peregrinations, you are somewhat older, but you may be assured that if I had listened to a multitude of voices that were raised to persuade me I should have been now a quiet country gentleman ignorant of a multitude of things I am now acquainted with and probably never attained higher rank in life but that of a country Justice of the Peace."

## Introduction

Barbados is situated at 13° 10' north, about 150 km east of the Windward Islands of the Lesser Antilles. The island is 32 km long, 23 km broad at its widest dimension, and towards the central interior attains a maximum elevation of 340 m.

Lying just east of the Lesser Antillean volcanic forearc, Barbados is a pinnacle on the broad accretionary prism caused by east-west convergence between the North American and Caribbean plates (Speed and Larue, 1982). The island is composed of a core of deformed Eocene to Neogene marine sediments, exposed in the north-east as the Scotland District, capped by a series of gently buckled reef terraces that record its rapid and differential uplift during the Pleistocene (Taylor and Mann, 1991).

## Pleistocene reef terraces

Fifteen separate Pleistocene reef terraces (Figures 1 and 2) have been identified in this coral cap and represent an episodic record of reef development from 640 ka to 60 ka (Broecker et al., 1968; Mesolella et al., 1969; James et al., 1971; Matthews, 1973; Bender et al., 1979; Edwards et al., 1987; Schellmann and Radtke, 2004). The continuous uplift of the Island at rates of up to 0.5 mm/year have exhumed reefs that correspond to the last six or seven interglacial sea-level highstands, extending as far back as MIS-17 (Shackleton and Matthews, 1977; Fairbanks and Matthews, 1978; Speed and Cheng, 2004). Early advances in radiometric dating of corals established the absolute chronology of these highstand reefs and provided the first confirmation of the Croll–Milankovitch theory of the Quaternary Ice-Age, which holds that orbitally forced variation in northern-hemisphere summer insolation drives changes in ice volume and sea level (Mesolella et al., 1969). Although further improvement in dating precision has subsequently questioned this theory and suggested that deglacial sea-level rise preceded the orbitally forced rise in insolation (Gallup et al., 2002), the precise timing of that rise remains difficult to substantiate due to the subtle diagenetic exchange of U-series nuclides in the fossil corals (Blanchon and Eisenhauer, 2001; Scholz and Mangini, 2007).

## Reef zonation

Aiding the comparison of reef terraces of different ages has been the remarkable stability in their zonation over time, (Mesolella, 1967; James et al., 1971) consisting of:

- A forereef facies of steeply dipping calcarenites and coral rubble, sometimes partially buried by the back reef facies of the next lower and younger terrace.

constitutes lime muds and bioturbated muddy lime sands with isolated colonies of branching corals.

Thickness of these facies varies, determined by the rate of relative sea-level rise at the time of their construction, for example, the *A. palmata* zones can have a vertical thickness of 20 m.

### Diagenesis and caliche

Barbados is an excellent field site for studying diagenesis and caliche formation (Figure 3). In the more arid south and west, aragonite and Mg calcite may be retained in corals

and other organisms for 300 ky (thousand years). In the more humid west, Mg calcite is absent for the 83 ky reefs and aragonite is not found in anything older than 200 ky.

Caliche (calcrete), the product of diagenetic modification at and immediately below the rock-soil/air interface is common on many of the Pleistocene reef terraces of Barbados. The caliche profiles vary from thin, relatively dense, laminated brown micritic crusts to horizons over 1 m in thickness comprising brown micritic stringers subparallel to the surface and cutting through the host structure or substrate (Harrison, 1977; Humphrey, 1997).

**Barbados, Figure 3** A brecciated caliche profile with numerous brown micritic stringers developed in Pleistocene (c. 83,000 yr) limestone on Barbados (Photo: courtesy D. Hopley).

## Submerged reefs

Submerged reefs formed during the post-glacial transgression are also found in Barbados, Macintyre (1967) recognized two offshore ridges that parallel most of the west coast at depths of 15–20 m and 70 m. However, further work quoted in Macintyre et al. (2007a), has shown an impressive series of backstepping of reefs dominated by *A. palmata* starting at depths of about <120 m and flourishing ~19 kya to ~14 kya, which were then stranded by the meltwater pulse 1a when the reef could not keep up with the rate of sea-level rise. A further reef was established to shoreward at a present depth of about –80 m forming 25 m of framework before it too “gave up” in response to meltwater pulse 1b (11.3–11.0 kya). Blanchon and Shaw (1995) identified a further reef at the shelf edge at ca –40 m, which “gave up” ~7.6 kya –6.5 kya in response to a further meltwater pulse. This has been a point of some contention and continued discussion (Blanchon, 2005; Toscano and Macintyre, 2005). While Blanchon has suggested that the composite sea-level curve has been smoothed by incorporating transported clasts, Toscano and Macintyre have justified the lack of a visible “jump” in their curve at about 7.6 ka as being the result of sea level starting to rise above the shelf edge at this time and the resulting “inimical” shelf waters causing the demise of reefs for a short period through sedimentation and eutrophication, rather than a rapid rise in sea level. Factors that need consideration in differentiating between the two arguments include the range with which *A. palmata* can be found (at least 5 m and possibly more on structures such as spurs and grooves) and then extended by storm deposited clasts (>5 m). Also, Barbados’ mean uplift rate of ~34 cm/ka is not steady but irregular in occurrence. Further, the *A. palmata* C<sup>14</sup> dates may not provide an accurate framework for rapid sea-level changes (Toscano and Macintyre, 2003; Bard, 1998). Nonetheless, the reefs of Barbados, both submerged and emerged provide

a source of Quaternary environmental data matched by few places elsewhere. For example, dating of the reefs that developed between each of these jumps also further constrained the offset between the radiocarbon and calendar timescale and were subsequently used to establish a standardized protocol for correcting the radiocarbon ages beyond 10 ka tree-ring record (Bard et al., 1990; Fairbanks et al., 2005).

## *Acropora palmata* demise and the origin of Cobblers Reef

Goreau (1959) was the first to identify the dominant role of *A. palmata* in Caribbean reef zonation. However, concern has been expressed over the widespread loss of this species since the 1980s (see Macintyre et al., 2007a, b, for references). The dominant cause has been white band disease.

*A. palmata* is a dominant component of Pleistocene reefs of Barbados (Figure 4) but as noted initially by Lewis (1960), like elsewhere in the Caribbean there is a distinct paucity of this coral in the modern fringing reefs, although Lewis (1984) later found *A. palmata* was forming the foundation upon which modern reefs were growing. However, more recent studies, especially of Cobblers Reef along the southern shores of Barbados, have led to conflicting interpretations of the evidence for the demise of *A. palmata* on the island.

Cobblers Reef forms a significant bank barrier reef 15 km long on the south-eastern shores of Barbados with a history of vigorous *A. palmata* growth which is now dead, covered by a rich algal growth and sparse living non-acroporid corals (Macintyre et al., 2007b). Dating of *A. palmata* clasts from this reef suggested various storm damage about 4,500 to 3,000 cal years ago with subsequent high energy conditions limiting herbivory and

Barbados, Figure 4 Reef crest *Acropora palmata* in 83,000-year terrace, Barbados (Photo: courtesy D. Hopley).

favoring algal growth, thus limiting the reestablishment of reef framework. A few in situ framework dates are only a few hundred years old, but this late period of growth is believed to have succumbed to high turbidity and eutrophication following clearing for agriculture from the mid 1600s (Macintyre et al., 2007a, b). However, an alternative view has been put forward by Blanchon who believes that hurricane emplacement of older clasts onto the crest of modern reefs, is not valid evidence of the timing of reef demise, which should be established from the age range of in-place colonies from cores through the reef deposit itself. There is the suggestion of a 500–400-year old reef under at least a meter of storm deposit. Such a reef would have grown to about 0.5 m below sea level when covered by storm deposits about 300 years ago. As the reef crest is now 2 m below sea-level, this would require the erosion of ~2.5 m of reef before the storm rubble was deposited. It is possible that both interpretations can be accommodated though not at the high energy Cobblers Reef site. Elsewhere on Barbados in more sheltered locations, reef growth may have continued until European settlement and clearance.

### Hydrogeology (Humphrey, 1997)

The porous and permeable Pleistocene coral cap of Barbados permits ground water recharge where precipitation exceeds evaporation in the higher parts of the island. The Tertiary sediments of the Scotland District provide an aquiclude that prevents downwards movement of water and where this lies above sea level, groundwater flows along the base of the limestones in underground streams. However, towards the coast where the aquiclude lies below sea level, a coastal phreatic freshwater wedge and associated mixing zone are developed. Meteoric vadose, meteoric phreatic and mixing zone waters interact with the young subaerially exposed limestones, resulting in a wide range of diagenetic modification. Barbados provides an excellent source of information for geohydrology and diagenesis in uplifted coral reef environments.

### Conclusion

Reef development in the uplifted and submerged reef terraces and their modern counterparts have yielded an exceptional number of important scientific advances and are a valuable resource that will ensure that Barbados continues to be a focal point for studies of both reefs and quaternary climate change. The past history of study and easy accessibility are two factors that add to this value. Many questions related to, for example, the detailed uplift history of the island still require answers, which may become more precise with advances in dating techniques.

## BARRIER REEF (RIBBON REEF)

Serge Andréfouët<sup>1</sup>, Guy Cabioch<sup>2</sup>

<sup>1</sup>Institut de Recherche pour le Développement, Anse Vata, Noumea, New Caledonia

<sup>2</sup>Institut de Recherche pour le Développement Centre d'Ile de France, Bondy CEDEX, France

## Definition and introduction

In Battistini et al. (1975), barrier reefs are defined as “a set of coral reefs separated from a non-reefal land by a deep lagoon.” This definition is based on morphology, specifically on the relative position between a land mass (itself not the product of the reef, like a reef island for instance), a lagoon, and a reef. With this definition, an atoll rim is not a barrier reef. Other definitions of barrier reefs are related to their genesis. Darwin (1842) explained their formation by the progressive subsidence of fringing reefs surrounding a volcanic island, slowly creating a lagoon between the barrier reef and the land. After complete disappearance of the island, only barrier reefs remain at the periphery of the system, forming atolls. Thus, atoll rims should also be considered as part of the barrier reef category with this definition. The two types of criteria, modern morphology, and geological genetic processes lead to conflicts. Modern views suggest to first label a reef as a “barrier reef,” according to its modern morphology and configuration within a set of land masses and reef complexes, and then study the local and global genetic geological-scale processes that explain the local barrier-reef morphology.

Ribbon Reefs is a term used to describe the outer shelf reefs of the Northern Great Barrier Reef, from 15° S off Cooktown up to 10° S in the Torres Strait. They are sequentially named by numbers (Ribbon Reef No 1, Ribbon Reef No 2, etc.). By similarity, the term has been applied to linear, long, winding reefs, including atoll rims and large banks, but it is not of common use.

Although demonstrated by deep coring projects into Pacific Ocean atolls (Mururoa atoll), the Darwinian fringing-barrier-atoll genetic succession can be applied to only a limited number of oceanic configurations worldwide. Instead, the role of a number of factors need to be taken into account: subsidence, antecedent substrate available for Holocene coral colonization and growth, eustatic sea-level variations, freshwater dissolution during the period of emergence at low-sea stands, and local tectonic processes are often necessary to explain the modern morphology. The relative importance of these factors is still debated to explain barrier reef morphology (Purdy and Winterer, 2006).

## Morphology

Classification of reefs using their planar, view-from-above, morphology as indicators of their genesis is common practice. In a barrier reef context, Hopley (1982) discussed for the Great Barrier Reef the validity of the

previous classifications obtained from the interpretation of aerial photography, but he accounted for new data from coring and from recent advances in understanding reef growth. He showed that previous interpretations could be misleading to infer a reef-growth development typology. Then, Hopley (1982) established a new classification for the shelf reef of the Great Barrier Reef, including as a specific zone the northern Ribbon Reefs, which display a typical barrier morphology, with linear reefs parallel to the continent, from 15° S up to 10° S in the Torres Strait. South of Cooktown, the Great Barrier Reef consists of a dense (e.g., the Swains group) to open matrix (e.g., the Capricorn Bunker group) of shelf patch reefs, also called platform reefs. The size of these patch reefs displays a wide range, from a few hundreds of square meters to several tens of square kilometers. The unique and photogenic Pompey Group, at 21° S displays a general barrier linear morphology, with very large individual reefs characterized by subsurface karstic formations, blue holes, and numerous deep and narrow channels.

Recently, remote sensing technology provided complete coverage of reefs worldwide using high spatial resolution Landsat satellite images (Andréfouët et al., 2006a). This new data set allows examining in details all barrier reefs worldwide. A detailed typology was inferred, although it cannot be precisely coupled in most locations with coring data to relate planar morphology with genetic processes like in Hopley (1982). Thus far, this link has been done only for New Caledonia (Andréfouët et al., 2009a). Nevertheless, the diversity of morphologies are potential indicators of local processes keeping in mind the same caveats that Hopley (1982) put forth for the interpretation of Great Barrier Reef structures.

Landsat images suggested a hierarchical typology that can be applied to oceanic and continental reefs. In this typology, atolls are described separately, and thus atoll rims are not considered like barrier reefs. First, two main types of barrier reefs are distinguished on the top of the hierarchy: the outer shelf and intra-shelf barrier. The intra-shelf barrier is composed of continuous lines of reefs in a lagoon, well separated from the outer shelf barrier. Then, these two types of barrier reefs can themselves be separated into barrier, multiple-barrier, faro-barrier, imbricated-barrier, coastal-barrier, and fringing-barrier types. Multiple-barriers are made of series of parallel reef flats developed close to each other and sometimes connected together (see Guilcher, 1988). A faro-barrier is a structure made of faros, or in other words a series of reefs with a central enclosed lagoon. An imbricated-barrier is a section of barrier, which is turning around itself, the outer side turning to the inner side when bending, thus changing completely the degree of exposure and the types of habitats. An imbricated-barrier can also be a barrier that terminates in the lagoon of a second separate barrier. A coastal-barrier is an intermediate configuration between a barrier and a fringing reef, that is, there is no deep lagoon, but a shallow sedimentary terrace that clearly separates outer reef flat habitats from fringing-like habitats.

A fringing-barrier is a section of barrier that harbors large islands, thus displaying fringing-type habitats in an outer barrier environment. Examples of all these barrier reef types are given in Figure 1. These types describe the diversity of barrier reefs worldwide based on their morphology visible on remote-sensing images.

## Locations

Beside the Australian Great Barrier Reef discussed above, barrier reefs are found in all coral reef provinces worldwide. In the Caribbean Seas and Atlantic Ocean, the longest system is offshore Belize, approximately 200 km long (Figure 1). This Belizean section is actually the only true outer barrier system of the so-called Meso-American Barrier Reef System (Mexican Yucatan, Belize, Guatemala and Honduras), which includes fringing reefs for most of its length. Honduras Bay Islands include a drowned barrier structure and narrow coastal barrier systems. In the Bahamas, Andros Island is often cited as having one of the longest barriers in the Caribbean-Atlantic region, or even in the world, but it is a fringing and coastal barrier system, without any deep lagoon. Other small barrier systems are found in Caribbean Panama, Columbian Islands (e.g., Providence Island), Venezuela (Los Roques), Greater Antilles (especially Cuba, but also Haiti and Dominican Republic) and Lesser Antilles (e.g., Guadeloupe), and in the Bahamas (e.g., north of Little Bahama Bank).

In the Indian Ocean, the longest system is a nearly 1,000 km long drowned structure along the west coast of Madagascar, at the edge of the shelf. It is poorly documented, and was absent in the region coral reef maps until recently (Andréfouët et al., 2009b), although it is visible in marine charts of this area. Southwest Madagascar (the Toliara region), Mayotte Island, and on the other side of the Mozambique channel, Mozambique, Kenya, and Tanzania (e.g., the Tanga area) have small sections of barrier reefs, including coastal barrier systems. Barrier reefs occur in Mauritius Island at various stages of development (Montaggioni, 2005). The large outer Seychelles plateau, also a deep subtidal system, present a barrier-like peripheral structure formed by large deep, drowned, platforms intersected by deep passes. In the Eastern Indian Ocean, the west coast of Australia displays the Ningaloo Reef system. It is generally described as a fringing reef, but its structure and habitat zonations are consistent with the definition of a coastal barrier reef.

The Red Sea has unique reef morphologies (Purkis, et al., 2010), and several areas can be classified as barrier reefs especially in Saudi Arabia (e.g., Al Wadj Bank area), Egypt (tip of the Sinai Peninsula), and South Sudan. Most of the Red Sea is bordered by fringing structures, which for the widest show coastal barrier like-patterns.

Southeast Asia (especially in the Philippines and Indonesia), including Japan (Ryukyus Archipelago) display numerous significant barrier reefs at various stage of development (e.g., Spermonde Barrier Reef), from coastal to outer barrier reefs, including drowned ones (e.g., east of

**Barrier Reef (Ribbon Reef), Figure 1** Examples of outer barrier reef morphologies captured with the Landsat 7 spaceborne sensor. All images have been rotated for a better comparison. Scales are different. (a) A section of the Belize barrier reef with a narrow intertidal reef flat, (b) a double barrier reef on the east coast of New Caledonia, (c) a coastal barrier reef on the West Coast of New Caledonia, (d) a partly drowned, partly intertidal barrier reef on the southeast coast of New Caledonia, (e) an imbricated barrier reef on the southwest coast of New Caledonia; differences between reef flat structures when the reef is bending are evidenced in this example, (f) a fringing-barrier reef in New Georgia, Solomon Islands, (g) a faro-barrier reef, on the west side of Suddest Island, in eastern Papua New Guinea.

the Aceh province of Indonesia). Most of these Asian reefs remain poorly studied (Tomascik et al., 1997).

The home of the most significant barrier reefs is the Western Pacific (Figure 2). Besides the Ribbon Reefs of

the Great Barrier Reef, which span 1,200 km, New Caledonia is surrounded by an intertidal 1,300 km long barrier that includes a large variety of morphologies (Figure 1). The Eastern region of Papua New Guinea, also harbor

**Barrier Reef (Ribbon Reef), Figure 2** Examples of Pacific Ocean barrier reefs captured with the Landsat 7 spaceborne sensor. (a) A section of the Great Sea Reef north of Vanua Levu, Fiji. (b) The barrier reef, partly intertidal, partly drowned that surrounds Mangareva Island in southeast French Polynesia. from Port Moresby (Papuan Barrier Reef, partly drowned) to the tip of the Archipel de la Louisiade (Calvados Barrier Reef, a 570 km long reef around Suddest Island), an uninterrupted stretch of morphologically diverse barrier reefs (Andréfouët et al., 2006b). This region also includes faro-barrier reefs (Figure 1). Other spectacular Pacific Ocean barrier reefs are the Fijian Great Sea Reef in the north of Vanua Levu Island (410 km) and the barrier reefs surrounding Palau Island (390 km). Pacific Islands from

Micronesia, Melanesia, and Polynesia display many barrier reefs of few tens of kilometers long, some that can be typically Darwinian (e.g., Bora Bora or Mangareva in French Polynesia, Aitutaki in the Cook Islands).

#### Drilling in barrier reefs

Only a few cores have been retrieved from the large barrier reef tracts, including in New Caledonia (Coudray, 1976;

Cabioch et al., 2008), Belize (Gischler et al., 2000, 2010; Purdy et al., 2003; Mazzullo, 2006), and the Australian Great Barrier Reef (Alexander et al., 2001; Webster and Davies, 2003; Braithwaite et al., 2004; Hopley et al., 2007).

Coring analyses of the barrier reef tract around New Caledonia revealed the interplay between margin subsidence and eustatic sea-level variations. Combination of lithological and paleoecological descriptions, Uranium dating methods, magnetostratigraphy, and nannofossil-based biostratigraphy document the role of both global climate and regional tectonic history on the reef initiation and growth of the barrier reef. Several successive lithological units were evidenced formed during the high sea stands of the interglacial periods. It appears that the period ranging over the last 400 ka (1 ka = 1,000 years) was probably the period of optimal conditions to explain the luxuriant reef expansion in New Caledonia over this epoch (Flamand et al., 2008; Cabioch et al., 2008).

In French Polynesia, the Tahiti barrier reef was cored to analyze the history of its development during the last deglacial sea-level rise (i.e., the last 20 ka, 1 ka = 1,000 years). The first cores made in the 1990s revealed a continuous reef growth from 14 to 6 ka from 90 m to the reef surface (Bard et al., 1996; Montaggioni et al., 1997). More recently, the Integrated Ocean Drilling Program (IODP) drilled the Tahiti barrier reef in three sites to investigate reef development during the last deglacial sea-level rise, and the evolution of the sea surface temperature during the last deglaciation (Camoin et al., 2007).

The Belize barrier reef is another well-studied reef, but only with short cores that document the Holocene and late interglacial period of growth. Additional seismic and lithological data provide information on the tectonic and eustatic controls on the Belize barrier reef development (Mazzullo, 2006).

The Great Barrier Reef internal Pleistocene structure remains poorly known. Davies and Peederman (1998), Alexander et al. (2001), Webster and Davies (2003), Braithwaite et al. (2004), and Braithwaite and Montaggioni (2009) report limited deep coring data given the extent of the system (see *Great Barrier Reef: Origin, Evolution, and Modern Development*). The most recent studies suggest that the Ribbon Reef No 5 was initiated 770 ka ago, followed by Pleistocene repetitive period of reef development and erosion with ten identified depositional units, despite major fluctuations on sea level and perhaps climate. IODP ongoing drilling (February–March 2010) should provide new information in the near future on the development of the Ribbon Reefs in particular, and for several other inner shelf locations as well.

## BASSETT EDGES

Roger McLean  
 University of New South Wales, Canberra, ACT, Australia

## Synonyms

[Bassett edges](#); Exposed edge of strata inclined upward; Outcrop; Strike ridges.

## Definition

Bassett edges are outcrops of inclined beds, forming a jagged surface of low irregular projections resulting from differential erosion of often steeply dipping layers

of lithified coral shingle, with a bed thickness of a few centimeters and relative relief of 2–3 dm.

A bassett is an old term used by miners in the 18th and 19th centuries to describe the emergence of subsurface geological strata at the ground surface. “Bassett edges” was introduced into the modern reef literature by J. Alfred Steers (*Steers, James Alfred (1899–1987)*) to describe the lower cemented vestiges of coral shingle ramparts on Australia's Great Barrier Reef, where “the separate beds are often truncated and the bassett edges rise up” (*Steers, 1929*).

What Steers found particularly interesting was the dip of the beds, which was “very often landward,” implying “that the rest of the spit or ridge of shingle formerly existed to the windward of the present outcrop.” Thus, the presence of low strike ridges that dip away from the reef front preserve the remains of old shingle rampart systems that have subsequently been eroded.

A more formal description and explanation of bassett edges on reefs of the northern Great Barrier Reef was given by Scoffin and McLean (*1978*). They found that (1) the inclined bedding of bassett edges represent the cemented foreset layers of the leading edge of shingle ramparts; (2) the irregular projections result from differential erosion related to subtle differences in the degree of cementation and constituent texture; (3) cements are typically a chalky micrite of high magnesium calcite; (4) bedding occurs as steeply dipping foresets (40–70°) on tongue shapes, like anticlines plunging to leeward, and as shallowly dipping (20–40°) arcuate bands between; (5) the inner buried portions of ramparts have to remain stationary for some time to allow lithification; and that is why (6) bassett edges are commonly found on the central and inner parts of a reef flat rather than toward the outer edge where wave action continually mobilizes rampart rubble.

Though the cemented foreset beds of shingle ramparts are not restricted to the Great Barrier Reef, the term bassett edges is not in common use in other reef areas.

## BEACH ROCK

Roger McLean  
 University of New South Wales, Canberra, ACT, Australia

## Synonyms

[Beach rock](#); Beach sandstone

## Definition

Beach rock results from lithification of unconsolidated sediments by calcium carbonate cements in the tidal zone of mainly tropical and subtropical beaches. Aragonite and calcite, in a number of crystalline forms, are the primary agents of cementation. All kinds of beach sediments can be cemented, from fine sands to gravels of biogenic and/or terrigenous origin. Beach rocks can also vary greatly in texture and degree of lithification, some being quite porous and friable, others being dense and highly indurated. Beach rock takes on the disposition of the parent beach, including the preservation of beach slopes and stratigraphy. Outcrops usually show a number of distinct bands that represent the bedding planes, internal laminae, and sedimentary structures preserved during the cementing process which can be quite rapid.

## Description

Beach rocks are a common and conspicuous feature of many island and mainland shores in reefal areas. They vary from small discontinuous exposures of cemented sediments to extensive outcrops tens of meters wide and hundreds of meters long. More normally, beach rock occurs as narrow elongate strips, 5–20 m wide and 100–200 m long, comprising an overlapping sequence of separate bands with a definite seaward dip varying from 5 to 15°. The thickness of individual bands is usually around 0.1–0.2 m with the total thickness of outcrops ranging from 0.5 m to more than 2.5 m, being thickest in areas of high tidal range. Banding is often associated with textural bedding, while the seaward dipping layers are characteristic of foreshore sedimentation. Different lithofacies have been recognized both in the vertical and within a single band.

Beach rocks generally occur in the swash zone of a beach and frequently mobile sand or gravel obscures the upper and/or lower portion of an outcrop. Temporary burial and exposure of formations may result from seasonal deposition and erosion of local beach sediments, or from alternating storm and fair weather regimes. Relic beach rocks may be found either landward, or more commonly, seaward of the present beach.

Beach rock is not the only cemented rock on coral coasts and reef islands. Others include conglomerates (*Conglomerates*), cemented platforms (*Platforms Cemented*), phosphate rock, *Eolianite*, and cay sandstone or cay rock, the last often being confused with beach rock *sensu stricto*, although the distinction between beach rock and cay rock is made quite clear by Gischler and Lomando (1997).

## Distribution

In a recent review Voudoukas et al. (2007) note that, until the early 1960s, the prevailing opinion had been that beach rock formation, involving carbonate cements, was primarily limited to tropical and subtropical coasts. However, subsequent observations have shown beach rock is

also present on temperate and higher latitude coasts with individual occurrences reported from South Africa and New Zealand in the southern hemisphere and Japan and Scotland in the northern hemisphere. Nevertheless, the great majority of beach rocks are found in low latitude locations, although there are particularly extensive outcrops around the Mediterranean Sea. Microtidal coasts tend to be favored, although there are many outcrops along island shores in areas of high tidal range such as in the central and southern Great Barrier Reef, Australia where tidal ranges of 2.5–8 m occur. There, and in other reef areas, beach rock is mainly associated with calcium carbonate beaches, and on coral atolls beach rock (*Beach Rock*) is generally the most common and obvious “rock” apart from biohermal reef rock.

## Grain size and composition

The grain size and composition of beach rock reflect that of the parent beach at the time of cementation. On coral reef coasts, beach rocks classically comprise a mix of sand- to gravel-sized sediments made up of the skeletal remains of calcareous organisms such as mollusks, benthonic foraminifera, coralline algae, and *Halimeda*, particularly in the sand to pebble size fraction. The coarsest components are frequently whole or fragmented coral clasts, especially of branching and foliaceous corals, and smaller massive corals as well as reworked fragments of reef rock and pieces of beach rock. There are also occurrences of beach rocks whose component grains are noncarbonate; volcanoclastic grains are common on volcanic islands, and quartzose sediments on rocky continental coasts. Many beach rocks also contain “erratic” materials, including exotic ballast rocks and even human artifacts and litter ranging from ancient pottery fragments to articles of war and modern beer cans and bottle glass.

## Cements

*Aragonite* and *Calcite* and especially high magnesium calcite are the predominant cementing agents of beach rocks. Both minerals are dimorphous with the same chemical composition (calcium carbonate) but different crystal shape and symmetry; aragonite is orthorhombic, and calcite is trigonal. Thin section microscope and scanning electron microscope images of beach rock cements reveal a wide range of morphologies and fabrics. Three common morphologies in tropical beach rocks were described by Scoffin and Stoddart (1983) as: micritic coatings of either aragonite or calcite on parent grains; fibrous or bladed crusts of elongate crystals commonly as aragonite; and classical equant crusts associated with magnesium calcite. They also described three common cement fabrics: isopachous fringes of uniform coatings around grains; meniscus cements; and gravitational or pendant cements. None of these fabrics are pore filling.

Voudoukas et al. (2007) suggest that well-cemented beach rocks may have undergone several diagenetic phases, each one producing cements of a different

mineralogy and habit. In sequence, beach rock cementation may commence with the precipitation of micritic cements around in situ grains, followed by the precipitation of prismatic crystal rinds, and finally pore filling, peloidal, spar, and infiltrating micrite cements. Changes to the nature and characteristics of cement types can also take place. Relic beach rock cements may show evidence of dissolution and/or recrystallization. A beautifully illustrated and described chronosequence of carbonate fabrics in 52 beach rock samples from the northeastern Mediterranean is presented in Desruelles et al. (2009).

### Origin of cement

While earlier descriptions exist of beach rock, including those of Darwin (*Darwin, Charles (1809–1882)*) and Dana (*Dana, James Dwight (1813–1895)*), the first detailed mineralogical and chemical analyses were carried out on samples from *Funafuti Atoll* collected during the Coral Boring Expeditions from 1896 to 1898. These analyses, together with thin section examination of several “calcareous sandstones” reported by David and Sweet (1904: 73–74), “shows the cement to be a fibrous radial calcite” and that the beach sandstones formed through the evaporation of calcium carbonate-charged fresh water oozing through an island’s intertidal beach sands, where “calcium carbonate would form and be deposited as cement between the sandy particles.” While there have been subsequent advocates of this fresh water lithification process, several other mechanisms have been proposed including: physicochemical precipitation from evaporating sea water or mixtures of meteoric water and sea water; the escape of CO<sub>2</sub> or degassing from groundwaters saturated with carbonates; and precipitation directly or indirectly through biological activity, especially by microbial cements (Khadkikar and Rajshekhar, 2003).

Detailed descriptions and illustrations of the range beach rock cements as well as modes of beach rock formation are summarized in a series of excellent reviews over the last several decades by Stoddart and Cann (1965) in the 1960s, Davies and Kinsey (1973) in the 1970s, Scoffin and Stoddart (1983) in the 1980s, Gischler and Lomando (1997) in the 1990s, and most recently by Voudoukas et al. (2007). These contributions provide episodic snapshots of the status of on-going beach rock research and its developments, especially related to the origin of beach rock. While beach rock origin has been the main matter of discussion over a long period of time, it is now quite clear that there is no one unique mechanism that results in the formation of beach rock, nor any exclusive set of environmental factors that control cementation.

Rather, beach rock formation is multigenetic, with a number of inorganic and organic formative processes, including direct cement precipitation from marine or fresh or mixed marine and meteoric waters, and cementation from biological processes notably microbial (fungi and bacteria) activity. Similarly, a range of factors appear to control cementation, including interstitial water

temperature, pH and salinity, through-flow and tide-level variations, the presence of calcium carbonate, organic compounds and microbes, as well as the stability of beach sediments, or as Gardiner (1903: 342) put it so quaintly “where the beach is at rest so far as growth outwards is concerned.” This list of factors is not exclusive, nor is their relative importance known for any beach rock site.

### Speed of cementation

Cementation can take place rapidly on time scales of a few years. Examples are provided by the incorporation of WWII relics into beach rocks on several islands across the Pacific and on the northern Great Barrier Reef. Gardiner (*Gardiner, John Stanley (1872–1946)*) reports on the removal of beach rock slabs for gravestones and building materials on the Fijian island of Rotuma and throughout the *Maldives* and their replacement by newly cemented or case hardened bands in a few months in the same location, suggesting a sustainability in local quarrying of beach rock. But perhaps the most famous example of beach rock formation is that reported in 1924 by Reginald Daly (*Daly, Reginald Aldworth (1871–1957)*) from the Tortugas Marine Laboratory, where within 2 years of the 1910 storm depositing a fresh ridge of loose calcareous sand in the vicinity of the laboratory, the deposit had been lithified to a depth of about 0.75 m, forming a band of typical beach rock.

### Age of beach rock and problems of dating

Beach rock cements are clearly younger than the grains and clasts that make up the bulk of the rock. Moreover, in reefal areas both the sediment and cement are composed of calcium carbonate. Thus, dating of whole-rock samples is problematical and will give ages based on the relative proportions of the original skeletal components and secondary cements, both of which are likely to be quite variable. Constituent clasts may be dated to obtain a maximum age, but to get an age closer to the time of beach rock formation, the cement must be dated. Obtaining an adequate amount of uncontaminated cement is challenging, and there is always the possibility of multigenerational cementation and recrystallization. However, Desruelles et al. (2009) report on successfully extracting micrite cements from beach rock at two sites in Turkey and obtaining AMS dates for these cements.

Voudoukas et al. (2007) include the estimated age of exposed beach rocks from 20 locations around the world, only six of which are from modern coral reef areas. They believe that the majority of dated beach rocks are fossil forms, 1,000–5,000 years old, but admit that the abundance of recent beach rocks is likely to be underestimated.

In spite of a large and increasing number of radiometric dates from beach rock samples around the world, those from modern coral reef areas have had limited success in dating the time of formation. For example, corrected radiocarbon dates of five whole-rock and one shell sample

from beach rock on six cays in Belize range from AD 345 to 1435, although Gischler and Lomando (1997) note that these may not be reliable ages and should only be taken as an approximation. On the Great Barrier Reef, Chivas et al. (1986) extracted nine firmly cemented clam shells (*Tridacna*) from low intertidal beach rock at Lady Elliot Island. The beach rock was known to have formed during the twentieth century, although two of the three nonmodern clams had conventional radiocarbon ages of 1830 and 6540 yBP, indicating millennial scale reworking of these well-worn shells.

While still in its infancy, optically stimulated luminescence (OSL) and thermoluminescence (TL) dating on feldspar and quartz grains from beach rocks in northeastern Brazil has been carried out (Tatumi et al., 2003). This technique has limited potential in most coral reef areas where both beach rock components and cements comprise calcium carbonate.

### Morphodynamics and shoreline change

Beach rock formation alters the nature of the shoreline, and turns what was once a mobile beach into a rocky shore. In so doing the permeable character of the beach is changed to an impermeable barrier that precludes swash infiltration and inhibits seaward groundwater flows. Two effects of these changes can be noted. First, the impermeable ramp does not reduce swash uprush and backwash, and may result in run-up reaching higher levels than previously causing overtopping of the beach rock and scour behind it. Second, the impeded groundwater outflow is redirected to the sides and base of the outcrop which together with wave, current, and tidal actions can result in lateral erosion and undermining of outcrops. Thus, paradoxically, while beach rock can be an effective natural beach defense, equivalent to a revetment, like many other shore protection structures, edge effects can result in basal undercutting and lateral erosion. Evidence of the former is often expressed in cracks and fractures, sometimes in attractive tessellated patterns, as well as subsidence of beach rock bands and slabs. Evidence of the latter can include landward offset of the waterline and retreat of the nearby beach. The presence of beach rock also has a significant ecological impact, as surficial and interstitial flora and fauna of the mobile beach is replaced by assemblages of benthic organisms on beach rock substrate.

Beach rock, as a consolidated rock, provides an excellent marker of the actual shore position when it formed. Persistence of the “frozen beach” (Caldas et al., 2006) is dependent on the sediment budget for that shoreline sector. A positive budget can result in accretion, burying the outcrop landward of the new shore. A negative budget can result in beach erosion, isolating the beach rock outcrop to seaward. This latter scenario seems especially common on reef coasts and reef islands, where one or more lines of beach rock extend offshore. While outcrops parallel to the present shore are most common, some

amazing strandline patterns can be found. On atolls, lagoonward migration of reef islands is a common feature. In addition to leaving a trail of beach rock to seaward, continued lagoonward migration may ultimately expose lagoonward dipping beach rock (from the former lagoon shore) on the seaward beach. There are several examples of this on modern reef islands, although the best historical descriptions are from the Maldives (Gardiner, 1903) and Funafuti atoll (David and Sweet, 1904).

### Beach rock as a sea-level indicator

Not only can fossil beach rock be used to provide evidence of planimetric shoreline change, but because its vertical range is restricted to between tide marks, its value for paleo-sea level studies has long been recognized. Hopley (1986) has provided the most definitive study of beach rock as a sea-level marker, indicating its pros and cons. He concludes that it is not particularly reliable because the exact upper limit of formation is poorly constrained. Indeed, Kelletat (2006) has argued that the large vertical extent in some beach rock occurrences in microtidal locations may be ascribed to cementation in the supratidal zone, although this has been vigorously disputed (Knight, 2007).

Notwithstanding these reservations, relic beach rock is still seen as an important paleo-sea level marker, although rarely as the sole indicator. In reefal areas emphasis has been on detecting mid-late Holocene changes in sea level and specifically to identify whether or not there has been a sea-level high stand. Elevations of relic beach rock have contributed to confirming a sea level higher than present on *Cocos (Keeling) Islands*, the northern Great Barrier Reef, Cook Islands, French Polynesia, and elsewhere in the Pacific. Beyond the major reef areas, beach rock has also been used to develop more continuous sea-level histories, such as in northeast Brazil (*Brazil, Coral Reefs*) where beach rock elevations and AMS dating of mollusk fragments from 12 samples suggest that sea level was at  $-3$  m 7000 cal yBP, reached  $+1.3$  m about 5900 cal yBP, after which it fell in linear fashion to its present position (Caldas et al., 2006). And, on the Sardinia–Corsica coast in the Mediterranean numerous beach rock outcrops have been preserved along the shorelines and at different depths on the continental shelf down to  $-29$  m. These have been dated from 9705 to 180 (cal yBP) enabling Lambeck et al. (2004) to derive a detailed local sea-level history over the last 10,000 years.

### Surface features and beach rock erosion

Beach rock is a striking feature of coral reef coasts and reef islands. The contrast between fresh light-colored biogenic sands and darker beach rock outcrops is often quite stark. Most observers note the inclined, banded nature of intertidal outcrops, their low-relative relief and bare surfaces. In detail, however, beach rock surfaces are rarely bare, except where the substrate is being constantly scrubbed

by sediment-laden swash. Typically, there is a shore-parallel zonation of both morphological forms and biological organisms, the zonation frequently being expressed in different surface colors representing pigments of various microbial communities including cyanobacteria, algae, and fungi that inhabit the beach rock. Diez et al. (2007) show such communities can be dominated by cyanobacteria that fix nitrogen at night, and constitute important primary producers that provide the base of the intertidal and nearshore food webs.

Bioerosional agents including fish, echinoderms, worms, and mollusks feed on the microbial mats, and at the same time, scrape, bore, and burrow into the beach rock as do some of the blue-green algae (*Algae, Blue-Green Boring*). Many biolithophagic organisms produce distinctive micromorphological features such as boreholes, burrows, and tunnels, while others leave smaller traces like homing scars from limpets and tooth marks from parrot fish. The geological significance of bioerosion of beach rock was recognized several decades ago (McLean, 1974) and the rates and impact of a number of beach rock eroding taxa, including echinoderms and chitons continue to be investigated (e.g., Barbosa et al., 2008).

Kelletat (2006) has noted that many beach rocks are in a state of destruction. Mechanical erosion and abrasion of beach rock can result in smooth surfaces, as alluded to above, and to the development of rhythmic transverse furrows or grooves in the lower tidal zone, and potholes in the upper tidal zone. Other common features include undercuts, notches, fractures, and broken slabs caused by basal undermining, marginal scour, and breakage due to mechanical strain and weakness. In places, where beach rock outcrops have been exposed for a long time, upper surfaces often show a jagged pool and pinnacle topography or microkarst resulting from a combination of solution processes (*Solution Processes/Reef Erosion*) and *Bioerosion*.

Destruction of beach rock can also be the result of human activity, where outcrops are quarried like slates and used as paving stones, building and fencing materials and tombstones. Such usage is especially true on reef islands in atoll states where solid rock is sparse.

## BELIZE BARRIER AND ATOLL REEFS

Eberhard Gischler

Goethe-Universität, Frankfurt a.M., Germany

### Definition

The Belize barrier and atoll reefs form the largest modern reef system in the Atlantic Ocean. Belize, formerly British Honduras, is located in a subtropical climate with air temperatures from 25 to 29°C and water temperatures that range from 24 to 32°C on average (Wantland and Pusey, 1975). Trade winds blow from the east and northeast for most of the year. Climate is also influenced by the position of the intertropical convergence zone (ITCZ), which is positioned over Belize in the summer–fall causing elevated rainfall. The ITCZ moves to the south in winter–spring, which results in lower precipitation rates. Rainfall rates on the mainland increase from 150 cm/year in the north to >400 cm/year in the mountainous south. Belize is a microtidal area with a tidal range of <0.3 m. Major hurricanes have repeatedly hit Belize and are a major factor of reef development and disturbance (Stoddart, 1963). In 1998, a combination of a major hurricane and an extensive bleaching event led to a significant loss of live coral cover in the Belize reefs (Mumby, 1999; McField, 2000).

### Geomorphology

The Belize Barrier Reef is about 250 km long and almost continuous (Figure 1). It is located at the shelf margin. The distance to the coast increases from 25 km in the north to 50 km in the south. Likewise, water depth on the shelf increases from max. 5 to 50 m in the same direction (Figure 2). At the southern end, the reef forms a peculiar hook-shaped morphology. In the north, towards the Mexican (eastern Yucatan) coast, the barrier reef shelf margin transitions into a fringing reef. On the Belize shelf, thousands of coral patch reefs may be found. There are also small shelf atolls, some of which have characteristic rhomboid shapes (Figure 3). Fringing reefs are rare adjacent to the northern inner shelf coast; however, isolated nearshore reefs do occur on the southern shelf that is influenced by siliciclastic input. This is a curious observation, because it is contrary to common belief that coastal reefs should flourish and be abundant in carbonate rather than siliciclastic environments. The three offshore atolls vary in size from 200 to 525 km<sup>2</sup> (Stoddart, 1962; Gischler and Lomando, 1999). Glovers Reef has a typical atoll morphology with an almost continuous marginal reef enclosing an 18-m-deep lagoon. The lagoons of Lighthouse Reef and Turneffe Islands are only 6–8 m deep. The Turneffe lagoon is restricted due to a dense rim of mangroves; corals are rare and *Halimeda* occurs in great abundance. Both on the shelf and the atolls, hundreds of small islands occur, including sand islands, rubble islands,

mangrove islands, and combinations of these, which are locally called cays (Stoddart, 1965).

### Organisms and reef zonation

A large variety of corals, algae, mollusks, crustaceans, echinoderm, fish, and other reef-related organisms have been described from the Belize reefs. An excellent overview was given by Rützler and Macintyre (1982), based on quantitative studies conducted along a transect across the central barrier reef near Carrie Bow Cay, the location of the Smithsonian field station. Forty-eight stony coral species have been described. The most important reef-building corals include the branched *Acropora palmata*, the foliaceous *Agaricia* sp., and the hydrocoral *Millepora* sp. that predominate in forereef areas. Massive corals of the *Montastraea annularis* group may be found both in forereef and lagoonal or outer shelf regions. *Acropora cervicornis* used to be very common in backreef, lagoonal,

**Belize Barrier and Atoll Reefs, Figure 1** Satellite image of the Belize reef system. Barrier reef is 250 km long.

and shelf areas; however, it was significantly decimated by disease in recent years (Aronson and Precht, 1997). Coastal reefs and restricted lagoons are dominated by the tolerant *Siderastrea siderea*. Stoddart (1962), James et al. (1976), James and Ginsburg (1979), and Macintyre et al. (1987) defined zones in marginal reefs of Belize, largely based on the occurrence of corals and other invertebrates and algae and based on submarine topography (Figure 4). James and Ginsburg (1979) described the deep foreereef of Belize barrier and atoll reefs based on

submersible observations. At the base of the sloping foreereef in 15–40 m depth, they discovered a steep drop-off leading to an almost vertical wall that reaches down to 100–150 m depth. At the base of the wall, a sediment slope with rubble and larger blocks may be found.

### Sediments

The Belize shelf is a classic example of a mixed carbonate–siliciclastic system (Figure 5). Siliciclastics originating from the southern mainland (Maya Mountains) and carbonate largely produced on the outer shelf mix on the inner shelf to form marl. Purdy (1974) elaborated the first systematic sediment map of the Belize offshore area. Gischler and Lomando (1999) detailed sediment types on the offshore atolls. A compilation of existing data including a detailed sediment map covering the entire Belize offshore area may be found in Purdy and Gischler (2003). Eleven facies may be delineated on the Belize shelf and atolls, with corals, coralline algae, *Halimeda*, mollusks, and benthic foraminifera being the most common skeletal constituents. Abundant nonskeletal grains, largely peloids, occur only in shallow lagoon areas of Glovers and Lighthouse Reefs. Carbonate mud on the southern Belize shelf (Matthews, 1966) and in the atoll lagoons (Gischler and Zingeler, 2002) is largely of biogenic origin. The curious occurrence of high-magnesium-calcite (HMC)-rich sediments on the northern Belize shelf is a consequence of either the disintegration of micritized HMC skeletal grains (Reid et al., 1992) or HMC precipitation (Macintyre and Aronson, 2006). Whittings, suspensions of fine-grained carbonate potentially indicating precipitation of  $\text{CaCO}_3$  in the water column, have been observed on the northern Belize shelf (Purdy and Gischler, 2003).

## Geology

The low northern part of Belize is largely covered by Cenozoic limestone. The mountainous south of the country (Maya Mountains) is characterized by Paleozoic siliciclastics and magmatic rocks, fringed by Cretaceous limestone and dolostone (Figure 6). A series of NNE-trending normal faults characterize the structural grain of the Belize passive continental margin. The hanging walls of these major faults form the basement of the Belize reef system. Offshore exploration wells and seismics have shown that up to 3.5 km of Meso-Cenozoic carbonates overlie the Paleozoic basement around the barrier reef (Purdy et al., 2003). Cenozoic carbonates on the offshore atolls are up to 1 km thick. The thickness of Pleistocene reefs ranges from 100 to 150 m. Studies on Pleistocene reefs are based on limited outcrops and a few deep wells in the northeastern and southern parts of the country

(Mazzullo, 2006; Gischler et al., 2010) as well as on Pleistocene reef limestone recovered in shallow coreholes below Holocene reef deposits (Gischler, 2006a). Pleistocene facies may be compared to modern ones, with the exception of the occurrence of Pleistocene oolites in northern Belize. Based on the sedimentologic and stratigraphic analysis of a long piston core taken in the deep forereef east of the barrier reef, Droxler et al. (2003) came to the conclusion that the modern barrier reef, as source of carbonate detritus, only came into existence during the exceptionally long and warm marine isotope stage 11, some 400 kyBP.

## Late Quaternary reef development, sea level, and antecedent topography

Postglacial reef growth started >8.26 kyBP on the Belize Barrier Reef (Gischler and Hudson, 2004) and 7.78 kyBP

**Belize Barrier and Atoll Reefs, Figure 6** Simplified geologic-tectonic map of Belize.

on the offshore atolls (Gischler and Hudson, 1998) based on the analysis of shallow drilling (Figure 7). Holocene reef thickness ranges from 5 to >21 m (Gischler, 2008). Holocene reefs largely consist of branched (*A. palmata*, *A. cervicornis*) and massive (*Montastraea* sp., *Diploria* sp., *Siderastrea* sp.) corals, a well-cemented grainstone–

rudstone, and an unconsolidated rubble and sand facies. Reef accretion rates range from 0.46 to 7.5 m/kyr and average 3.03 m/kyr (Gischler, 2008). The Holocene sea-level curve of Belize is based on *A. palmata* and red mangrove radiometric age dates. The curve is transgressive and discussed controversially (Toscano and Macintyre,

**Belize Barrier and Atoll Reefs, Figure 7** Late Quaternary cores taken along Belize Barrier Reef, from north to south (from Gischler, 2008).

2003; Gischler, 2006b). Holocene reef lagoon development is ideally characterized by a succession of Pleistocene bedrock, dark soil, mangrove peat, shell bed (coquina), *Halimeda*-rich packstone, and mollusk-*Halimeda*-foram-rich wackestone and packstone, from bottom to top (Gischler, 2003). This succession is an expression of Holocene inundation by the rising sea and subsequent deepening. There is an ongoing controversy regarding the nature of the reef foundations. Based on coring, the basement of Holocene reefs on the offshore atolls and the barrier reef is Pleistocene limestone. Ferro et al. (1999) suggested that parts of the barrier reef platform were underlain by prograding siliciclastics, based on seismic investigations. The increase in reef thickness from north to south is thought to be an expression of both an increase in karst dissolution during Pleistocene sea-level lowstands and stronger subsidence in the same direction (Purdy, 1974; Gischler and Hudson, 2004). Holocene reefs on the Belize shelf are located both over Pleistocene limestone and siliciclastics (Purdy, 1974; Choi and Ginsburg, 1982). The former position of channel and river bars as well as incised valleys apparently was decisive for shaping antecedent topography and Holocene reef initiation (Esker et al., 1998; Ferro et al., 1999). Indeed, the rhomboid shape of some of the shelf reefs is reminiscent of channel bars. In addition, Lara (1993) and Purdy (1998) showed that faulting and folding was of importance for the formation of topographic highs and the subsequent initiation of reefs on the southern Belize shelf and southern barrier reef, respectively.

## Summary

The Belize reef system includes fringing, barrier, and atolls reefs as well as lagoonal patch reefs and lagoon atolls (faroos). The reefs, which are predominantly composed of corals (*Acropora* sp., *Montastraea* sp.) exhibit clear zonations. The Belize shelf is a classic example of a mixed carbonate-siliciclastic system, like many other large barrier reefs. Eleven modern sediment facies may be distinguished. The reef system of Belize is located on a passive continental margin with tilted fault blocks forming the basement. Both differential subsidence and variation in karst dissolution of underlying Pleistocene limestone determined patterns of late Quaternary reef accretion. Postglacial reef growth was extensive with thicknesses of >20 m and average accretion rates of 3 m/kyr.

## BERMUDA

Alan Logan<sup>1</sup>, Thaddeus Murdoch<sup>2</sup>

<sup>1</sup>University of New Brunswick, New Brunswick, Canada

<sup>2</sup>Bermuda Zoological Society, Flatts, Bermuda

## Definition and introduction

The British Overseas Territory of Bermuda, a crescent-shaped chain of about 150 islands, lies in the north-west Atlantic Ocean at 32°20'N and 64°45'W, about 1,500 km south of Halifax, NS. The regional setting and geological foundation of Bermuda's coral reefs are summarized in Logan (1992). Physiographically, Bermuda is an atoll, in that a peripheral annular reef tract and islands form a mostly submerged 26- by 52-km ellipse around

**Bermuda, Figure 1** Above: Aerial photograph of Bermuda, showing isobaths and main physiographic zones described in text. CH = Castle Harbour. A and B are end points of profile (below). Below: NW to SE profile across the Bermuda Platform along line A and B shown above: FR fore-reef slope; MT main terrace; R. rim; L. lagoon; I. Bermuda Islands; CH. Castle Harbour; CR. south shore algal cup reef tract (vertical exaggeration approx. 600).

a shallow central lagoon (Figure 1). The 20 m isobath separates this shallow platform from the fore-reef slope, with slopes of the latter rarely exceeding  $10^\circ$  seawards. The islands form the only emergent part of the Bermuda Seamount arising from 4,000 m depth and comprise a thin Pleistocene–Holocene carbonate sequence capping volcanic rocks below. The antecedent topography of this carbonate platform, formed from alternating periods of sediment movement and subaerial erosion in response to fluctuating Pleistocene sea levels, exerts a strong control over coral reef formation (Garrett and Scoffin, 1977), although the reefs are more than just veneers over the existing topography. Bermuda has the highest latitude reefs in the North Atlantic and owes its subtropical climate mainly to eddies of the warm Gulf Stream flowing into the Sargasso Sea. Nevertheless, the reefs show reduced biotic diversities compared to those in the Caribbean, with, for example, only about 40% of Jamaican coral and gorgonian species occurring in Bermuda but all of Bermudian species present in Jamaica (Logan, 1992; Logan, 1998). The coral *Acropora*, an important reef builder in the Caribbean, is a notable absentee in Bermuda, probably due to cool winter water temperatures, which average about  $18^\circ\text{C}$ .

### Major reef types and their communities

There are two major reef-building communities in Bermuda: a coral–algal consortium responsible for most of the reefs on and around the platform and the less common algal–vermetid gastropod cup reefs; found mainly around the edge of the platform, and particularly on the south-east side.

#### Fore-reef slope reefs

These reefs occur around the outside of the platform margin from 20 to 40 m depth and show total coral coverage values approximating 25%. The dominant corals, which account for over 85% of corals present (Logan, 1992), are large overlapping shingle-like colonies of *Montastrea franksi* (Figure 2) and domal heads of *Diploria strigosa* and *Montastrea cavernosa*. The bottom is highly irregular, with holes of 1–2 m relief between coral colonies. Understory species include *Porites astreoides* and *Diploria labyrinthiformis*, but coral diversity is low. Gorgonians are common, as is encrusting *Millepora alcicornis*, while coverage by species of the fleshy brown phaeophyte algae *Lobophora*, *Dictyota*, and *Stypopodium* can sometimes reach 25%, although this may be seasonal (Logan,

**Bermuda, Figure 2** Large colony of *Montastrea franksi* showing overlapping shingle-like growths, fore-reef slope reefs, North of North Rock, 28 m.

**Bermuda, Figure 3** Head corals and gorgonaceans in shallow wave-surge area, movement left and right. Note alignment of sea fans normal to wave direction, rim reefs of North Rock, depth 4 m.

1998). Because of their depth and distance from land, these reefs are the poorest known in Bermuda.

#### Main terrace reefs

These reefs succeed the fore-reef slope reefs at the platform margin, covering a prominent terrace extending from 10 to 20 m seawards from the annular rim reefs. From a narrow sediment apron at the outer edge of the rim reef tract, at a depth of about 5 m, a series of reef ridges, separated by sand channels, form an anastomosing pattern similar to spur-and-groove structure. This feature is particularly well shown along the western edge of the platform (Logan, 1988). Total coral coverage values for main terrace reefs are the highest in Bermuda, frequently reaching 50%, but coral diversity is again low. The bottom has less relief than that of the fore-reef slope and is dominated by domal colonies of the two species of *Diploria* (64%), encrusting or platy *Montastrea franksi* (32%), and domal *Porites astreoides* (3%). This *Diploria*–*Montastrea*–*Porites* reef-building community is typical of all platform margin and lagoonal coral–algal reefs across the platform.

#### Rim reefs

Rim reefs are developed on the elevated 100-km ring of shallow shoals that encircle the lagoon and protect it from open-ocean waves. These reefs extend lagoonwards by lobate extensions and grade into main terrace reefs on the seaward side. Their tops lie between 2 and 6 m depth and are dissected by ramifying sand channels of about 10–15 m depth. The reef tops show relief of about 1 m between coral heads, with about 22% coral coverage (Dodge et al., 1982). Large gorgonaceans belonging to at least six genera are attached to the reef tops and channel sides, taking advantage of the almost constant surge from the open ocean (Figure 3). The *Diploria*–*Montastrea*–*Porites* coral assemblage is again predominant, their

**Bermuda, Figure 4** Cavity at the base of reef between sand channels, rim reefs, North Rock, 9 m depth.

species accounting for over 90% of the coral coverage, with the two species of *Diploria* accounting for over 65% alone. A wide variety of coral growth forms occurs, from domal to encrusting to platy, presumably in response to varying light conditions. Sponges, zoanthids, hydrozoans, anemones, and corallimorphs are common, with smaller colonies of less common coral species present as understory species. Diverse coelobite communities colonize shaded areas beneath coral heads or in caves and tunnels near the base of the reef (Figure 4). While occasional diseased coral colonies are encountered, the rim reefs remain the most healthy and attractive reefs in Bermuda and appear to have been little affected by bleaching or anthropogenic influences.

#### Algal–vermetid cup reefs

These cup reefs, locally known as “boilers,” occur as a discontinuous tract on the outer edge of the platform

rim, particularly on the south-eastern side from St. David's Head to South-West Breakers, where there are three distinct zones, more or less parallel to the shoreline. The first zone comprises bioconstructional lips attached to headlands, the second is the present actively growing cup reef tract at the edge of the narrow rim (near-shore platform), and the third and oldest zone consists of drowned cup reefs furthest from the shore whose tops now lie at a depth of 10–12 m (Meischner and Meischner, 1977). These authors suggest that the latter were formerly at sea level about 7,000 years ago and that the bioconstructional lips will eventually become the actively growing tract as headlands are eroded. Cup reefs are generally circular to oval in shape (Figure 5) and less than 30 m in their maximum dimension. In profile they have an elevated rim awash at high tide, enclosing a shallow mini-lagoon with occasional small coral heads, and tapering to a narrow undercut base at 8–10 m depth (Logan, 1992). Void space is high in these reefs. The main constructive agents are crustose coralline algae and the partially embedded vermetid gastropod *Dendropoma corrodens*, with occasional encrusting *Millepora alcicornis*, all of which are adapted to turbulent conditions in high wave energy environments (Thomas and Stevens, 1991). Boring by sea urchins and sponges and intense

grazing by parrotfish are the main destructive agents. The algal-vermetid cup reefs represent an unusual reef type rarely found elsewhere in the world.

### Lagoonal reefs

Lagoonal reefs comprise patch reefs of many sizes and shapes in North Lagoon (Logan, 1992), the tops of which are close to the surface, with steep flanks grading off into lagoonal sands and muds at depths averaging 15 m. Coral coverage on the tops of lagoonal patch reefs is generally less than 40% (Dodge et al., 1982; Murdoch, 2007), although the flanks often reach 70% with species of *Diploria* and *Porites* dominating the outer reefs, *Montastrea* the central areas, and *Madracis* the nearshore reefs (Murdoch, 2007). The lagoonal reefs have higher coral diversity than the platform reefs, and in addition, support a rich sessile invertebrate biota of corals, gorgonaceans, zoanthids, sponges, anemones, tunicates, and bivalves, as well as a variety of calcified algae which act as sediment producers and binders. Grazing parrotfish increase in diversity and abundance as distance from land increases and are prodigious producers of fine sediments. The hydrozoan *Millepora alcicornis* in branching and encrusting growth forms is present on all lagoonal reefs, the branching form being particularly common on the nearshore reefs along the north shore.

### Inshore reefs

Of Bermuda's inshore waters, only Castle Harbour has significant reef development, where linear fringing reefs occur around the western and southern shorelines, and steep-sided patch (pinnacle) reefs are present in the north-western and south-eastern areas. Dredging for airport construction in 1941–1943 resulted in hydrographic changes and resuspension of fine sediments in the area which has had deleterious effects on both of these reef types (Dryer and Logan, 1978; Logan, 1992). Prior to the dredging, the waters of Castle Harbour were pristine and supported healthy reefs (see predredging accounts in Dryer and Logan, 1978); now living corals show only about 5% coverage on fringing reefs and 13% on patch reefs. The patch reefs are mainly of the pinnacle type, about 4–5 m high and 5 m wide, with irregular tops at depths of 1–2 m and with vertical or steep-sided walls. Dryer and Logan (1978) reported *Isophyllia sinuosa* and *Diploria labyrinthiformis* as the dominant corals on the reef tops, with coral coverage and diversity low, while the steep flanks showed relatively high coral coverage values of up to 50% by branching corals of *Oculina* and *Madracis* which are able to shed fine sediments efficiently. Since then, resurveys of Castle Harbour reefs by Cook et al. (1994) and Flood et al. (2005) indicate that *Diploria labyrinthiformis*, an efficient sediment shedder, is still the dominant species on reef tops, but active recruitment of *D. strigosa* is increasing the importance of this species. The branching coral *Madracis auretenra* continues to rank high in coverage on the pinnacle reef flanks,

**Bermuda, Figure 5** Aerial photo off Hungry Bay, south shore of Bermuda, showing nearshore platform (NP), line of actively forming cup reefs (boilers AB), drowned older boilers (DB), and dark smudge of sewage outfall (SO).

but *Oculina diffusa* appears to have declined since the 1978 survey, although Flood et al. (2005) suggest that this may be an artifact of the different survey methodologies used.

### Factors affecting Bermuda's reefs

While factors such as coral competitive interactions, reproductive activity, growth rates, and diseases can affect the composition of Bermuda's reefs (Logan, 1992, 1998), coral bleaching, pollution, and ship groundings are presently regarded as the most important, since they may pose a threat to the health of Bermuda's reefs in the long term.

### Coral bleaching

Episodes of extensive bleaching in Bermudian corals, coincident with periods of elevated summer water temperatures, occurred in 1988, 1991, 1997–1998, and 2003, with minor bleaching in other years, but the long-term impact of these episodes has been remarkably slight, with coral mortality low at less than 2%. The most detailed studies were done on the 1988 and 1991 events by Cook et al. (1990, 1994) who showed that in both years the species most affected was the hydrozoan *Millepora alcicornis*, with lesser effects on *Montastrea franksi*, *Diploria labyrinthiformis*, and *Porites astreoides*. In 1988 water temperatures were the highest in the previous 38 years (over 28°C offshore), with platform margin rim reefs the most affected. In contrast, Bermuda's lagoonal reefs experienced the most bleaching in the 1997–1998 bleaching event, with *Millepora alcicornis* again the most affected species. Cook et al. (1990) suggested that Bermuda's high latitude corals are thermally sensitive to elevated temperatures that are within the normal thermal tolerance range for corals at lower latitudes, indicating that thermal tolerance in reef corals is inversely related to latitude.

### Pollution and ship groundings

Jones (2008) surveyed main terrace coral reefs lying 300 m from a daily discharge of 2.5 million liters of untreated sewage from the Hungry Bay outfall on the south shore of Bermuda. He concluded that there is little or no evidence of adverse environmental effects on the reefs over the previous decade, in terms of species composition, abundance, and incidence of coral diseases.

The resuspension of sediments by dredging in Castle Harbour has already been mentioned, but sediment resuspension by ship propellers is another form of anthropogenic pollution which can have harmful effects on reefs. Unfortunately, most of this takes place through two shipping channels that cross the central lagoon where otherwise healthy reefs are abundant. Increases in the sizes of ships have led to a call to dredge and substantially alter the path of the shipping channels, which is likely to have a harmful effect on the condition of lagoonal and rim reefs.

A previously serious problem was the effect of ship groundings, which was studied by Cook et al. (1994). They listed the major ship groundings from 1940 to

1993 and concluded that damaged sites have been extremely slow to recover, mainly because of poor recruitment and slow growth of corals, particularly *Diploria* (Smith, 1992). They estimated a period of 100–150 years for coral coverage and species diversity to be restored on such reefs. Predictably, reef fish populations in these areas have been reduced and may remain so until sufficient coral growth has accrued. One further problem is the possible inhibition of recruitment from biocides in antifouling paint from the hulls of grounded ships (Jones, 2007). To prevent any further risks to the Bermuda reefs, the Bermuda government has set up a sophisticated radar surveillance system which has effectively prevented further grounding since 1993. This system permits the monitoring of vessel movements to ensure that they keep clear of the International Maritime Organisation (IMO) and International Association of Marine Aids to Navigation and Lighthouse Authorities (IALA)-sanctioned Area To Be Avoided – a 20 nautical mile “no go” zone around the island to protect Bermuda's reefs. However, since 2000, a dramatic increase in marina and nearshore development, the addition of larger cruise ships, and a new ship pier appear to be just the start of an increase in large-scale negative impacts on the marine environment, indicating the need for stronger planning policies and better resource management.

### Summary

Bermuda at 32°N supports the highest latitude coral reefs in the North Atlantic and one of the highest in the world. Algal-vermetid cup reefs, particularly well developed off the south shore of the island, represent an unusual reef type rarely found elsewhere in the world. While corals, the main reef builders, show lower diversity than the Caribbean, presumably in response to cool winter water temperatures, nevertheless the main physiographic zones of fore-reef slope, main terrace, rim, and lagoon all support thriving coral reefs which have as yet been little affected by coral bleaching or anthropogenic influences such as pollution and ship groundings. Only reefs in the inshore waters of Castle Harbour have suffered long-term deleterious effects from extensive dredging for airfield construction in 1941–1943. However, there is a need for stronger planning policies and better resource management in the whole area if the Bermuda reefs are to remain healthy and protected.

## BIKINI ATOLL, MARSHALL ISLANDS

James E. Maragos

U.S. Fish and Wildlife Service, Honolulu, HI, USA

### Definition

Bikini Atoll lies in the northern Marshall Islands in the central Pacific. It is 694 km<sup>2</sup> with a perimeter of 122 km. Its central lagoon is up to >30 m deep. There were originally 25 islands on the rim but several of these were destroyed by the Nuclear testing carried out on the Atoll in the 1950s.

### Introduction

The Marshall Islands archipelago consists of 29 atolls and five isolated reef islands with a combined total of 1,136 low reef islets, 174 km<sup>2</sup> of land areas, 13,000 km<sup>2</sup> of lagoon areas, and 2,600 km of reef circumferences. As a whole, the Marshall Islands are located in Micronesia, situated at the east of the Mariana Islands, northeast of the Caroline Islands, and northwest of the Gilbert Islands (Figure 1). The Marshall Is. support the oldest and largest atolls in the Pacific and the world and consist of two northwest to southeast trending ridges, the *Ralik* to the west and *Ratak* to the east, each with separate atolls, islands, cultural lineages, and traditional leadership. Bikini Atoll (11° 37' N and 165° 23' E) is at the north end of the western chain, with its closest neighbors Enewetak and Ujelang atolls lying 150–200 km to the west, and Rongelap and Ailinginae Atolls 50 km to the east.

Bikini is a rectangular atoll, with its long axis being 46 km from east to west, and varying from 15 to 19 km along the north–south axis (Figure 2). The combined reef and lagoon area of the atoll is 694 km<sup>2</sup>, total land area is about 6 km<sup>2</sup>, and total perimeter reef circumference is 122 km. Bikini consisted of 25 islands until two and a half of them were destroyed by the hydrogen bomb “Bravo” test in 1954. Overall, Bikini Atoll ranks tenth in terms of total reef and lagoon area and 11th in terms of land area among the Marshall Islands. Bikini lies in the northern arid Marshall Islands and supports less vegetation, groundwater, rainfall (1450 mm per year), and human populations compared to those in the central and southern Marshall Islands. However, rainfall is highly variable ranging from 600 to 2,400 mm per year. Surface ocean water temperatures normally range from 25 to 29°C per year.

### Physical environment

Bikini's low coral islets are 3–4 m above the mean sea level and concentrated on the east and southwest rims of the atoll. The western and northeast rims emerge at low tide but are nearly devoid of islets. The largest islet, Bikini (2.14 km<sup>2</sup>) is at the northeast corner of the atoll, and the four next largest islets in descending size are Eneu (Enyu)

**Bikini Atoll, Marshall Islands, Figure 1** Vicinity map of eastern Micronesia and the Marshall Islands (after the Bikini Atoll Rehabilitation Committee, 1987).

at the southeast corner, Nam on the northwest rim, Enidrik on the southeast rim, and Aerokojlol on the south rim. All eight of the passes at Bikini cut through the elongated south rim of the atoll, with the longest (16 km) and shallowest (5–20 m depth) pass at the southeast corner of the atoll just west of Eneu Island. A cluster of seven narrow but deep passes (>30 m) bisect the southwest perimeter reef. The prevailing northeast trade winds generate

wind waves that break on windward reefs and, via wave set-up, continually drives water across the reef flats into the northeastern lagoon regardless of the state of the tide. These cooler waters then sink toward the bottom of the lagoon, spiral within broad cells, and eventually discharge through the passes and over leeward western reef crests (Figure 3). The eastern lagoon is calm and sheltered from the trade winds by the eastern perimeter reef and islands.

However, the wind fetch 20 km or more to the west generates steep wind waves of up to 2 m in height in the central and west lagoon during normal wind conditions, rendering small boat navigation hazardous during the heavy winds and seas.

### Scientific surveys at Bikini Atoll

The geological structure, composition, and morphology of Bikini Atoll were thoroughly studied before and after the initial Operation Crossroads atomic bomb tests at Bikini in 1946. Samples were collected at many sites via shallow hookah diving, free-diving, and by hand on shallow patch reefs in the lagoon and on both sides of the perimeter reef

and reef crests in 1946–1947. Extensive collections were also made of corals and geological samples via dozens of deep dredge hauls of the lagoon floor and seaward fore reefs to depths of 60 m and more. Two deep drill cores were also obtained and analyzed from Bikini and later compared to those taken at Enewetak (Figure 4; see also *Enewetak Atoll, Marshall Islands*). The two Bikini drill holes penetrated to depths of 1,346 and 2,556 ft and extended well into Tertiary reef deposits but did not reach basalt volcanic rock as was the case for the Enewetak drill holes. The bottom half of the longer of the two Bikini cores was mostly composed of unlithified sediments and primary aragonite, yielding fossil corals, calcareous algae,

Bikini Atoll, Marshall Islands, Figure 4 Comparative composition of Bikini and Enewetak drill cores (after Schlanger, 1963).

**Bikini Atoll, Marshall Islands, Figure 5** Vertical cross section and geomorphological zones along the windward reef rim of Bikini Atoll (after Emery et al., 1954; Ristvet, 1987).

and foraminifera. The intervals and Pleistocene unconformities in the Bikini cores were consistent with those of the Enewetak cores. After a hiatus of 2 decades, more recent studies on archaeology, corals, vegetation, birds, sea turtles, and fish were accomplished in the mid 1980s, with corals and fish surveyed again in 2002.

The geomorphology of windward reefs and the east lagoon was extensively mapped and studied. Reef characteristics at Bikini were found to be similar to those of Enewetak and other atolls in the Marshall Islands. Major reef zones along the windward side of the atoll from off-shore to the lagoon are diagrammed on Figures 5 and include:

- Seaward slope
- Sea terrace
- Algal ridge
- Coral algal zone
- Seaward reef flat
- Islet or inter-island reef crest
- Lagoon reef flat
- Lagoon terrace
- Lagoon floor or basin
- Coral knolls (pinnacle and patch reefs)

Exceptional galleries (room and pillars) have also been reported on the windward reef flat off Bikini Island. Numerous patch and pinnacle reefs were surveyed and studied at Bikini throughout the lagoon, and eastern lagoon sediments were mapped in detail (Figure 6).

### Marine biology

Extensive surveys of stony corals were accomplished at Bikini by three separate investigators in 1947–1948, 1985, and 2002. When combining the updated and corrected lists of all three, 283 species of shallow stony corals have been reported from Bikini, the most of any surveyed atoll in the world. In addition, John Wells

**Bikini Atoll, Marshall Islands, Figure 6** Composition of lagoon sediments in the eastern rim of Bikini Atoll (after Emery et al., 1954).

also reported fossil species and a dozen deep water azooxanthellate stony corals species (Wells, 1954a, b). The high numbers of contemporary species are attributed to the extensive combined observation and collecting

efforts in all major habitats, deep and shallow at Bikini. In comparison, lesser collecting and observational efforts to depths of 30 m have yielded about 180 species of stony corals at Enewetak, 175 at Arno, 180 at Ailinginae, 205 at Majuro (the second highest totals to date in the Marshall Islands), and 203 species at Helen Atoll in southwestern Palau. The latter Bikini surveys in 1985 and 2002 relied primarily on scuba diving, and both documented prolific recovery of corals within 27–44 years of the end of the nuclear testing program.

The first comprehensive fish surveys in 1985 were focused on estimates of species likely to be consumed by the returning Bikini People and are not a comprehensive inventory of all species. Yet, 250 species at 29 sites were reported by Agegian et al. (1987). Later, Pinca et al. (2002) independently conducted fish surveys at Bikini and accounted for 359 species, but a combined list of both the investigations was not compiled. Randall and Randall reported more than 800 fish species at Enewetak based on extensive observations and diverse collections including poison stations to account for cryptic species. Thus, the higher diversity of fish species at Enewetak is attributed to considerably more survey effort and methods. In comparison, 267 fish species were reported at nearby Ailinginae Atoll at 33 sites in 2002. As with the 1985 Bikini survey, the emphasis on the Ailinginae surveys included preferential attention to larger fish, and thus, many cryptic and smaller species were not inventoried. Bikini fish biomass and abundance was reported high in both fish surveys.

## Vegetation

Fosberg (1988) surveyed ten islets including four of the five largest at the atoll in 1985, (Figure 7). He organized his surveys based on prior analysis of aerial photographs of Bikini obtained during the 1978 radiological aerial survey of the Northern Marshall Islands (see Tipton and Meibaum, 1981). Fosberg compiled 65 plant species and noted that most native species were still present at the atoll including stands of the beach forest tree *Pisonia*, a globally imperiled IUCN red-listed genus, on several islets on the western half of the atoll. However, other intact stands of native vegetation were decimated from copra production during the German and Japanese occupations and followed by nuclear weapons testing and related infrastructure development. Fosberg's overall conclusion was "On the islets mapped in any detail for the present survey, no unaltered vegetation has survived. . . The present vegetation still contains most of the species present in pre-nuclear times. . . and a few species have disappeared. In addition a number of exotics have appeared and some have become common. . . Recovery of vegetation after the nuclear tests has been rapid, but with a high proportion of pioneer species." Fosberg recommended protective status for the six tiny islets on the southwest reef on the basis of their high natural diversity and bird and turtle populations.

**Bikini Atoll, Marshall Islands, Figure 7** F. Raymond Fosberg surveying the vegetation at Bikini Atoll in 1984 (source: J.E. Maragos).

## Seabirds and shorebirds

Bird surveys were conducted by Garrett and Schreiber at 12 islets at Bikini Atoll in May 1986, and they compiled a combined total of 26 bird species compared to an earlier survey of 17 birds in 1969, three of which were not seen in the 1986 survey. The higher latter totals were attributed to much greater survey effort and revealed the presence of 14 species of seabirds and a resident reef heron, with ten of the seabird and the heron species likely nesting at Bikini. The seabirds included four shearwaters: (*Puffinus pacificus*, *P. bulleri*, *P. griseus*, *P. tenuirostris*), Red-tailed Tropicbird (*Phaethon rubricauda*), Great Frigatebird (*Fregata minor*), Red Footed and Brown boobies (*Sula sula*, *S. leucogaster*), four terns (*Sterna bergii*, *S. sumatrana*, *S. oahuensis*, *Gygis alba*), two Noddies (*Anous stolidus*, *A. minutus*), and the Eastern Reef Heron (*Egretta sacra*). Additionally, migratory species included the Laughing Gull (*Larus atricilla*) and seven Arctic shorebird species: Lesser Golden Plover (*Pluvialis dominica*), Wandering Tattler (*Heteroscelus incanus*), Gray-tailed Tattler (*H. brevipes*), Whimbrel (*Numenius phaeopus*), Bristle-thighed Curlew (*N. tahitiensis*), Ruddy Turnstone (*Arenaria interpres*), and Sanderling (*Calidris alba*). Three of the bird species: Buller's Shearwater (*P. bulleri*), Sooty Shearwater (*P. griseus*), and the Curlew are red-listed by IUCN.

At-sea observations by the ornithological team revealed 12 species including one species, the Pomarine Jaeger, not reported during land surveys at Bikini Atoll. Overall,

the 1986 team concluded that the avifauna of Bikini is “typical of low coral atolls in the region, with significant nesting populations of several species of seabirds. . . It is likely that most or all current populations of Bikini Atoll seabirds represent recolonization occurring after the conclusion of atomic bomb testing.” The presence of many ground-nesting seabirds at the atoll suggests that some of the outer islets were free of rodents, although the latter were noticeably abundant on the main islands. Birds were again surveyed at Bikini in 2002, and the authors suggested that the absence of islanders at the atoll over many years may be benefiting seabird populations.

### Sea turtles

Hawksbill turtles (*Eretmochelys imbricata*) and green turtles (*Chelonia mydas*) were commonly observed swimming on ocean reefs and lagoon habitats during marine biological surveys from 1984 to 1986. The seabird team, Garrett and Schreiber (1988) also searched for turtle tracks and pits during their surveys of 12 islets in 1986, and they reported seeing a few nests and tracks only at Bikini Island.

### Atmospheric nuclear tests at Bikini

The nuclear program at Bikini totaled 23 tests from 1946 to 1958 and was the first site for the U.S. Pacific Proving Ground. The location, yield, crater diameter (if any), and code name for each test are provided in Figure 8. The first two tests, *Able* and *Baker* of Operation Crossroads in 1946, were conducted 5 km east of the north end of Bikini Island. At the time, WWII had just ended, and there was little knowledge of the destructive power of fission bombs. The goal of Operation Crossroads was to determine whether such weapons could disable and sink large warships in battle-ready condition (fully armed and fueled). The two detonations were public events, witnessed by politicians and press from many nations. Hundreds of American warships with approximately 42,000 sailors participated in the tests, with the manned ships anchored at increasing distances away to observe and document the effects of the blasts. About two dozen unmanned and derelict vessels, including three captured during the war, were placed as targets near ground zero, and about half of the occupied ships were positioned close enough to be intentionally exposed to radioactive fallout from the blasts to assess its effects. Several ships carried livestock as

**Bikini Atoll, Marshall Islands, Figure 8** Map showing location, crater size, code name, yield, and date of 23 nuclear tests at Bikini Atoll from 1946 to 1958 (after Richards et al. 2008).

**Bikini Atoll, Marshall Islands, Figure 9** Baker atomic bomb test in east Bikini Lagoon, 1946, showing upward entrainment of two target ships in the cylindrical upheaval of seawater just after detonation (source: U.S. Government photo).

a proxy for assessing the possible impact of radiation on humans.

The first test *Able* was an air drop that detonated at 300 m above the lagoon within 1 km north of the targets, and results of the test were inconclusive although several of the ships were sunk. The device for the second test *Baker* was submerged at a depth of 30 m in the lagoon, and its detonation instantaneously thrust over 1,500,000 m<sup>3</sup> of contaminated seawater a mile high within the first second (Figure 9) carrying at least two ships with it. In turn, this generated huge waves radiating away from the blast that tossed large warships out of the water and sinking eight of them. Although never noted, these waves may have washed up on nearby Bikini Island, possibly responsible for contaminating the potable groundwater beneath the island that later proved to be a major hurdle for the resettlement of the island. The *Baker* test also evaporated vast amounts of seawater, creating a massive radioactive condensation cloud that contaminated many of the islands and manned ships (Figure 10). After the second test, the crews for the flotilla of observer warships swabbed, scrubbed, and washed down their decks but could not rid radioactivity from many of the vessels. The ships and crews then returned to ports scattered all over the globe. Some of the contaminated ships were too “hot” and were sunk. Less information is available on the fate of their crews. Baker appears to have been the first and last open underwater test during Marshall Islands nuclear era.

After a hiatus of 8 years, additional nuclear tests at Bikini were conducted from 1954 to 1958 (Figure 8). These were much further to the west of the main inhabited islands, and all were surface or barge detonations except one additional airdrop (Dakota 1956, 1 megaton (MT) yield). During the Operation Castle, six very large tests from 6.9 to 15 MT were detonated along the north rim near Aomen and Nam Islands and included one fizzle (Koon) along the south rim near Enemaan Island. The largest

**Bikini Atoll, Marshall Islands, Figure 10** Baker atomic bomb test in east Bikini Lagoon, 1946, showing expansion of condensation cloud shortly after detonation (source: U.S. Government photo).

atmospheric test in history was the Bravo blast detonated at the end of a reef flat causeway 970 m southwest of Nam Island, the first deployable dry fuel hydrogen bomb developed by the United States. Its actual yield (15 MT) was 2.5 times its predicted, and the blast evaporated the underlying reef, two islets, and part of a third island (Nam). The resulting crater measured 2 km in diameter and 80 m deep (Figures 11a–c). The blast was accompanied by intense super-heated air and contaminated debris that rose more than 35 km that may have contributed to stratospheric wind shift from northward to eastward that led to the radioactive fallout over a broad area up to 300 km from the blast. The fallout rained down on five other atolls (uninhabited Eniwetok, Rongerik, and Ailinginae and inhabited Rongelap, Utrik), and also

**Bikini Atoll, Marshall Islands, Figure 11** Northwest rim of Bikini Atoll before and after the hydrogen bomb test Bravo at Bikini Atoll in 1954: (a) Pre-test view of Nam and two islands to the west (source: unpublished U.S. government map, circa 1947). (b) Post-test (1978) aerial photo view of the same scene showing Bravo Crater, damaged Nam Island, disappearance of two other islets to the west, and scour trenches along the north face of the crater (source: EG&G Electronics 1978; see Tipton and Meibaum 1981). Post test (2005) view of the same scene showing coralline algae recovery on the northern reef rim, including a 1 km scale bar at top of aerial photo [after Google Earth, Digital Globe and the U.S. National Aeronautical and Space Administration (NASA)].

contaminated a Japanese fishing boat (*Daigo Fukuryū-Maru*) that resulted in one death. Although the afflicted atoll inhabitants were quickly evacuated after the blast, many later suffered from radiation sickness. During the subsequent half century, corals and anemones have recolonized Bravo Crater, and crustose coralline algae are now evident on the reef flats scoured, trenched, and fractured by the 1954 blast (Figure 11c). During Operation Redwing in 1956, several other barge-placed bombs of lesser yield (3.5–5 MT) were detonated in the north and northeast lagoon, and another surface test was detonated at the south crater site near Enemaan I. The northern test, Tewa (5 MT), created a large half crater along the north rim (Figure 12).

International pressure for a moratorium on atmospheric nuclear testing led to a final flurry of eight U.S. tests, including three fizzles, under Operation Hardtack in 1958 at Bikini. These included one large test (Poplar, 9.3 MT) and four smaller tests in Bravo Crater, and three smaller tests conducted in Enemaan Crater (Figure 13). The U.S. signing of the Partial Test Ban Treaty of 1963 ended all further underwater and atmospheric testing by the United States and other signatory nations. Since 1956 at least \$759 million has been paid to Marshall Islands, and \$15.3 million paid to Japan following the Bravo accident.

### Early cultural history

Extensive archaeological surveys in 1984–1987 included testing and dating at Bikini Atoll and revealed that:

- Eneu Island may have been settled more than 2,000 years BP
- Bikini Island may have been occupied beginning between 3890 and 1960 years BP, and
- Bikini Island may have been continuously occupied from 600 years BP

**Bikini Atoll, Marshall Islands, Figure 12** Aerial photo view (1978) of the Tewa 1956 bomb crater along the northeast rim of Bikini Atoll (source: EG&G Electronics in Tipton and Meibaum 1981).

**Bikini Atoll, Marshall Islands, Figure 13** Aerial photo view (1978) of the Enemaan Crater (southeast rim of Bikini Atoll) created by several nuclear tests at Bikini from 1956 to 1958 (source: EG&G Electronics in Tipton and Meibaum 1981).

The first two of these findings are still among the oldest cultural dates yet reported for Micronesia outside the Mariana Islands. The Bikini evidence relied on 18 radiocarbon dates, 58 confirmed indigenous artifacts, and several post holes and charcoal pits from an ancient village site eroding at one of the atoll shorelines. Moreover, the Marshallese legends and stories are consistent with the archaeological evidence and suggest that people began inhabiting the archipelago 2,000–3,500 years ago. Bikini oral history suggests that a chief (*iroij*) and his people first traveled from Wotje Atoll to Rongelap Atoll with a later generation of the clan led by a chief Larkelon who eventually arrived at Bikini and displacing the then existing residents at the atoll. The modern Bikini people can still trace their lineage back to Larkelon. The Bikini people were known for their large ocean-going sailing canoes and ability to travel and navigate over long distances. Similar to the situation with the Enewetak people, the Bikini people were sufficiently isolated and independent from other inhabited atolls and not subject to the rule of higher chiefs (*Iroij laplap*) until the last century. The early residents were also able to gain sufficient sustenance from the land and sea to maintain their culture over many centuries, and enhancing their independence and isolation.

### Recent history

The Spanish explorer Saaverda and his ship *Florida* in 1528 is credited as the first westerner to make contact with the residents of “Los Jardines,” either Bikini or Enewetak atoll. Although English explorers visited several neighboring Marshall Islands in 1788, no other Europeans visited Bikini again for nearly four centuries until 1825, when the German explorer Otto von Kotzebue sighted Bikini from a distance and naming the atoll “Escholtz” after the ship’s surgeon in 1823. Another possible visit by a trading schooner at Bikini in 1834 led to a confrontation with local residents resulting in casualties on both

sides. In 1858, Chramtschenko, Kotzebue’s former lieutenant, returned to Bikini, entering the lagoon. German copra traders began visiting the Marshalls in the 1860s, and by 1885 Germany claimed the Marshalls, Marianas (except Guam), and Carolines as protectorates. The copra trade was concentrated in the southern and central Marshalls where rainfall and production was much higher. Although small scale copra trading occurred at Bikini, no Germans ever settled on the atoll, and the Bikini people maintained their isolation, customs, dialect, and self rule until the dawn of the twentieth century.

In 1908 a Marshallese pastor arrived to establish the first Christian mission at Bikini. In 1914, Japan seized the Marshalls from Germany after the outbreak of WWI and retained them after Germany’s defeat, via a League of Nations Mandate in 1919. Japan promoted trade and development until the early 1930s but then closed the Marshalls and their other Pacific territories to outsiders and began fortifying many of the atolls, in violation of the earlier Mandate. During WWII, many residents of Bikini became indentured laborers assisting Japanese troops at Bikini who constructed a watchtower to guard against a possible American invasion. Young male residents were later sent to other islands to assist in the construction of other garrisons. Bikini continued to serve as an outpost during the remainder of the war. After the Pacific war ended in 1945, the United States assumed control of the Marshall Islands. In 1947, the new United Nations formalized U.S. custody of the Marshall, Caroline, and Mariana archipelagos as the Trust Territory of the Pacific Islands (TTPI). The overall goal of the arrangement was to prepare the peoples of the TTPI for self government. However, in March 1946, the U.S. planned to use of Bikini and Enewetak Atolls as part of the new Pacific Proving Ground for nuclear weapons testing.

### The nuclear nomads of Bikini

Commodore Ben H. Wyatt, military governor of the Marshalls District, reached agreement with the leaders of the Bikini People to use Bikini “for the good of mankind and to end all world wars.” As a result, the Bikini People were required to leave their home atoll and were moved to uninhabited Rongerik Atoll, to the east of inhabited Rongelap Atoll. Rongerik was small, exposed to heavy seas, and provided insufficient food for the new residents, and in 1948, the Bikini People were evacuated again to a tent city on Kwajalein Atoll until a permanent settlement site could be found. Eventually, the Bikini People chose to settle on Kili, a small single island in the southern Marshalls lacking a lagoon, a protective anchorage, and ocean access during seasons and periods of heavy seas. However, the island was favored by the settlers because it was not under the rule of any paramount chief and was uninhabited. Eventually, Kili was viewed as a prison, due to limitations on ocean access, inhabitants highly dependent on outside canned food and other essentials, and irregular visits by supply ships during heavy weather. At times, emergencies required air drops of food and vital supplies.

In 1967, after numerous radiological surveys at Bikini, the U.S. Atomic Energy Commission (AEC) concluded that Bikini was safe for re-habitation, and in 1968 President Johnson ordered the rehabilitation of Bikini. However, the Bikini Council visited Bikini and later decided against returning there due to concerns over the contamination of coconut crabs and other radiological safety hazards, but the leadership allowed individual families to choose for themselves. Three extended families and about 50 other Marshallese workers opted to return to Bikini Island in 1969. The rest of the 540 People of Bikini remained at Kili. After 5 years the population at Bikini had grown to 100. The U.S. continued efforts to cleanup the atoll, construct housing, replant coconut trees, move off all military and AEC personnel, and discontinue regular air service to Bikini by late 1972.

However, several U.S. agencies warned of “higher levels of radioactivity than originally thought” . . . “Bikini appears to be hotter or questionable as to safety” . . . and the “groundwater was too contaminated to be consumed as drinking water.” Later AEC scientists revealed that locally grown foods, especially coconuts, pandanus, breadfruit, and coconut crabs bio-accumulate hazardous radio-nuclides including Cesium<sup>137</sup> and Strontium<sup>90</sup>. Later medical tests of the islanders revealed low levels of Plutonium<sup>239</sup> and Plutonium<sup>240</sup>, radio-nuclides with half lives of thousands of years. Confused by the reports provided by the U.S., the Bikini People filed suit in federal court demanding the U.S. to complete a scientific survey of Bikini and the other northern Marshall Islands. In 1978, the U.S. agreed to accomplish an aerial radiological survey of the Northern Marshalls. Unaware of the extent of the radiological danger, the settlers opted to remain on Bikini Island until the studies were completed. However, by May 1977, levels of Strontium<sup>90</sup> in the well water exceeded the maximum U.S. limits, and a month later another study revealed that “all living patterns involving Bikini Island exceeded federal guidelines for 30 year population doses.” Moreover, U.S. scientists recorded a major increase in Cesium<sup>137</sup> body burdens in the majority of the people living on Bikini I. Alarmed by these findings, the U.S. Department of Interior (DOI) advised the settlers to limit consumption of one coconut per day and to begin shipping in food from outside the atoll. However, in April 1978 medical examination of the islanders revealed that radiation levels were well above the maximum permissible level in many of the 139 people on Bikini, and by May 1978, DOI described the 75% increase in Cesium<sup>137</sup> as “incredible.” Hence, all islanders at Bikini were evacuated to Ejit Island on Majuro Atoll in September 1978, where the community remains to this day. Meanwhile, the main population of the Bikini people continues to live on Kili Island.

### Restoration for resettlement

Over the next 3 decades, the U.S. evaluated various options for the safe return of the Bikini People to their home atoll. Lawrence Livermore and Brookhaven National Laboratories

assessed the physical options and maintained medical support for all people exposed to radiation. Distrustful of U.S. Government Agencies and Laboratories, the Bikini People petitioned the U.S. Congress to fund independent bodies to evaluate and advise them on the pros and cons of various options to restore Bikini for the safe return and habitation at Bikini Atoll. The first of these was the Bikini Atoll Rehabilitation Committee (BARC) consisting of several highly regarded scientists and engineers in the fields of medicine, radiation, physics, engineering, soils, and agriculture, and the present writer served as the environmental specialist for BARC from 1984 to 1987. BARC concluded that habilitation of Bikini Island’s groundwater to potable levels was not possible and suggested a smaller permanent settlement at Eneu Island where the environment is free of radiological contamination. As for safe resettlement options at Bikini Island, BARC proposed four doable options:

- Removing all topsoil from Bikini Island and possibly replacing it with clean soil
- Saturating the soil with fertilizer containing potassium, an element of similar properties to radioactive cesium and strontium that would be preferentially taken up by crops
- Soak the soil with seawater which has abundant sodium that would block the uptake of radioactive cesium and strontium, but would render the soil unusable for agriculture
- Buy land with reparations funds from the U.S. Nuclear Claims Tribunal and live somewhere else until Bikini’s radioactive cesium and strontium decay to safe levels: the two radio-nuclides have half lives of 28–30 years, meaning the soil would be safe within two to three centuries

In the 1990s, the Bikini People hired their own advisors and have recently solicited the advice of the International Atomic Energy Agency for evaluation and advice. However, the People of Bikini have not accepted or pursued any permanent alternative to this date. The one exception was opening up the atoll to small-scale sport and technical diving over the past decade. The sunken shipwrecks, bomb craters and the prolific recovery of the coral reefs from past insults are attractions of major interest to many visitors.

### Summary and conclusions

Under present circumstances, it is uncertain that the Bikini People will soon return to Bikini Atoll. The 63 years that have passed since the residents were first removed from the atoll have instead led to the passing of most of the original residents. Only a few of the present Bikini population that now totals more than a thousand have spent much time or lived at Bikini. All are now a part of a vastly different socio-economic age and culture. Should a larger group of the Bikini People return to the atoll when it is again “safe,” global climate change may have already washed away some of the islands and any hope of resorting

a subsistence live style practiced by the former inhabitants. Perhaps, this may be the end of a chapter in human history where a small society was able to sustain itself and endure the rigors of nature and mankind for over several millennia, perhaps, among the longest any society has ever survived in a small space during this modern era of civilized humanity. In January 2009, the Kili-Bikini-Ejit Local Government and the Republic of the Marshall Islands nominated Bikini Atoll for World Heritage in early 2009. By the end of 2010, the World Heritage Committee will make its recommendation on whether the atoll will be inscribed as a World Heritage property.

### Current investigations, controversies, and gaps in current knowledge

Although much has been published about the people and the impacts caused by the nuclear testing in Bikini, there has been very little rigorous scientific research focused on the degree to which the coral reefs of Bikini have recovered after the 1950s. Buddemeier et al. (1974) sectioned the skeletons of corals that lived before and after the nuclear test era at neighboring Enewetak. Although comparable specimens were not collected at Bikini, the Enewetak results showed no evidence of consistent differences in growth rate in the annual band widths laid down by individual corals before and after the nuclear testing era. Moreover, Agegian et al. (1987), the present writer, and Richards et al. (2008) report many large coral heads thrive on Bravo Crater and virtually all pinnacles and patch reefs in the lagoon (Figure 14) and in the adjacent Nam Island rock quarry (Figure 15), where one large coral must have settled and began growing shortly after the Bravo test.

Richards et al. (2008) maintain that at least 28 species reported by Wells (1954b) before most of the nuclear tests “represent genuine losses” attributed to the nuclear testing program. This was based on comparisons of Wells species before the tests and the Richards team list 42 years after the final test. However, Richards implicitly assumes that both investigators accounted for all the species present at the atoll at the time of the surveys. Moreover, they did not consider the unpublished coral surveys of Maragos (1985) who reported 17 of the lost species at Bikini in 1985. More importantly, 49 species from Wells (1954b), 22 species from Maragos (1985), and 50 species from Richards et al. (2008) were not reported by the other respective investigators. The most likely explanation is that the “losses” is the incomplete compilation of all species by any of the three investigators. In fact, the Wells compilations were primarily based on deep water dredged hauls to depths of more than 60 m and shallower reef collections. In contrast, the other two investigators relied on scuba surveys at depths which were not readily accessible at the time of the Wells surveys. Moreover, many of the Wells-only species occur in deep water that could have only been collected by dredged hauls. Compiling all lists together and developing species accumulation curves for

**Bikini Atoll, Marshall Islands, Figure 14** View of top of pinnacle in eastern Bikini lagoon in 1985 showing luxuriant development of stony corals (*Acropora* spp.) 27 years after the termination of nuclear tests at the atoll (source: J.E. Maragos).

**Bikini Atoll, Marshall Islands, Figure 15** View of 1984 hemispherical coral head (2 m diameter) of *Porites lutea* that settled and grew in the rock quarry near Nam Island after the 1954 Bravo Test. Ground zero for the test was approximately 1.5 km from the quarry (source: J.E. Maragos).

the 29 Maragos (1985) sites reveal that the total list is still incomplete, and that there may be as many as 304 stony coral species based on bootstrap estimates.

Regardless, the coral reefs of Bikini Atoll deserve continuing analysis of their response and recovery from the

nuclear era and their prognosis during the global climate change of the future. Especially important is to continuing the monitoring of radio-nuclides in marine food webs and monitoring the abundance and distribution of reef biota at fixed sites over extended time. Such studies would likely benefit the future use and occupation, if any, by present and future generations of the Bikini People.

need firm substrates on which to settle. Binding and encrusting organisms such as encrusting sponges (Knott et al., 2006; Turon et al., 1998), foraminifers (Machado and Moraes, 2002; Perrin, 2009), or algae stabilize the loose carbonate grains and thus cement the reef body. The most important encrusting organisms of modern reefs are the light-dependent calcareous red algae (known also as coralline algae), but many other calcareous encrusting organisms exist including polychaetes, phoronid worms, chaetognaths (arrow worms), holothurianschordates (ascidians), foraminifera, corals, bivalves, algae, and bryozoans. These organisms bind sedimentary particles to create a living framework or shelter or the binding process is purely a by-product of the organisms' digestion and scavenging of the sedimentary environment for food. Although in most modern reefal environments, binding organisms are in the minority, they were responsible for building entire bioherms or reef systems in the geological past and thus during certain eras, binding organisms were much more widespread and common than today. However, even in modern times, binding organisms are critically important as they contribute calcium carbonates to the reef framework (Bianchi et al., 1995; Logan, 1961; Mallela, 2007; Perry, 2000), bind particles and rubble and thus stabilize the substrate (Fischer et al., 2000; Krasnow and Taghon, 1997; Rasmussen et al., 1993; Rasser and Riegl, 2002), and promote larval recruits and offer nutrients and habitats for other species such as bacteria, algae, and foraminifera (Davies et al., 1992, 1998; Maneveldt et al., 2006; Riemann and Helmke, 2002).

Duration of binding depends on several factors and few data are available. Preliminary stabilization by seagrass, uncalcified algae, or sponges may be rapid due to their fast growth, but these preliminary stabilizations last only 1 month to a few months (Rasser and Riegl, 2002), whilst rigid binding by encrusting coralline algae can take place within seven months. Interlocking of branched coralline algal crusts may take place within a few years, or within 1 year, depending on the growth rates of the particular species. In addition, binding activity that contributes to rapid encrusting and cementation is approximately double in fore-reef settings than in back-reef settings (Perry, 1999; Rasser and Riegl, 2002).

## Algal structures

Reefal environments contain many different algal communities pertinent to binding and accreting carbonate material. Algae form intricate growth patterns and species are often overlapping such as encrusting red algae or blue-green boring and epiphytic algae (Dean and Eggleston, 1975). The distribution and growth of these and other encrusting organisms depend on factors such as environment (fore reef, lagoon, etc.), substrate composition (soft sediments, corals, etc.), water depth and temperature, light level, turbidity, wave and current energy, and sediment influx (Mallela, 2007; Perry, 2000; Rasser and Riegl, 2002). Some encrusting algae commonly grow around

## Definition and introduction

Coral reef environments host many organisms that actively precipitate mineral matter and encrust or bind sedimentary particles together. In reef systems, waves, storms, and boring organisms constantly produce loose material (mostly skeletal debris), but reef organisms often

a nucleus (coral rubble, shell fragment, etc.) to form rhodoliths. These are common in reefal environments and growth rates of  $\sim 1.6$  mm/year have been determined (Ballantine et al., 2000), although much slower growth rates have also been suggested. In the Caribbean, filamentous algae are estimated to produce  $700 \text{ g C/m}^2/\text{year}$  and macroalgae  $1,170 \text{ g C/m}^2/\text{year}$  (Rasser and Riegl, 2002), whilst a study from Jamaica determined the carbonate production of coralline algae using artificial tiles to be between  $70$  and  $150 \text{ g/m}^2/\text{year}$  (Mallela, 2007).

Modern reefal environments contain abundant algal material but only few of those form mats and biofilms, which trap, bind, and cement sedimentary material and form accretionary structures. These binding structures of which the finer-bound matrix is preserved, called stromatolites, dominated the shallow shelves during early Earth (Allwood et al., 2006; Grotzinger and Knoll, 1999). At present, shallow marine stromatolites occur around the world but are often very limited in extent. The most famous modern stromatolite occurrences are in Shark Bay (Western Australia) (Logan, 1961), Lagoa Salgada (Brazil) (Lemos et al., 1994), Highborne Cay and Exuma Sound (Bahamas) (Dill et al., 1986; Dravis, 1983), Teikehau Atoll (French Polynesia), Chetumal Bay (Belize), etc. These structures are covered with biofilms of microorganisms (in Shark Bay  $\sim 90\%$  cyanobacteria and  $10\%$  archaea), which trap, bind, and cement sedimentary particles. Early work from Shark Bay showed that two major types of stromatolites exist: (1) the eualgal-cyanobacterial stromatolites (generally coarse grained) and (2) the cyanobacterial stromatolites (fine grained) (Awramik and Riding, 1988). There, the algal eukaryotes produce subtidal columnar stromatolites due to their extracellular gel formation, which trap and bind sediment and biogenic fragments (e.g., ooids, mollusks, diatoms). Similarly, the stromatolites from Exuma Sound (Bahamas) are also coarse grained with dasyclads and cyanobacteria, which trap sands that are then bound and cemented by acicular aragonite and chasmolithic green algae (Dravis, 1983). More recent investigations into the microorganisms associated with stromatolites demonstrated a uniquely high diverse community of cyanobacteria, bacteria, and archaea (Burns et al., 2004).

## Polychaetes

Sedentary polychaetes, including serpulids, sabellariids, and sabellids, are another important encrusting group of organisms. Most polychaetes have a tube constructed by sediment particles and mucus (organic compounds), in which they live or grow erect attached to each other, which may form large aggregates. The branchial crown of sabellids functions both in respiration and in the collection of suspended particulate matter from the surrounding water (Bonar, 1972). The tube formation is a consequence of burrowing as sand particles adhere to the mucous sheets secreted by the mucous cells of the epidermis. The first portion built of the tube is a small, transparent mucous

cylinder, about 2-mm long (Kirtley, 1994). The worms collect small fragments of minerals, diatom frustules, sponge spicules, and other small objects of manageable size and implant these reinforcements in the delicate mucus. Later in their tube building, the worms choose among a greater variety of materials. Into upper parts of the cylinder are set angular quartz grains, small fragments of broken mollusk shells, fecal pellets, and other materials – all arranged in an overlapping spiral pattern that rises to the base of the flared opening. Tube formation and growth of 2.5–5 cm may occur within 2 months (Naylor and Viles, 2000) and the tube particle sizes are often coarser than the mean particle size of surrounding sand. In addition, flat, platy and elongate particles are preferentially used. A study from Florida showed that most sand particles ranged between 0.25 and 0.5 mm (Main and Nelson, 1988). In the Caribbean, analysis of modern polychaete worm tubes showed distinct micritic peloidal lamellae morphologies (Fischer et al., 2000). Histological investigation of the tubes of *Dodecaceria* showed that the tube formation is related to two processes. The initial process is weakly controlled by the worm itself (matrix mediated). The worm produces acidic organic mucus substances, which are enriched between the soft tissue and the tube wall. The mucus has an antifouling capability and inhibits the mineralization of the mucus for a certain time. Within polychaete tubes, the mineralization events of the mucus are responsible for the stromatolitic microfabric of the tubes. Within the spaces between the primary lamellae, nonspecific extracellular polymeric substances-rich mucus is enriched, which controls the formation of fibrous aragonitic crystals and peloidal fabrics. Hence, the mucus plays an important role during the organomineralization process, which is not controlled directly by the organism (Fischer et al., 2000).

Sabellariid reefs flourish best where vigorous wave and current action cause the suspension and transport of sand-size particles (Kirtley, 1994). In some areas (e.g., east and northeast Brazil and southwest India), sabellariid reefs may extend laterally for thousands of kilometers along the shores of modern seas (Pandolfi et al., 1998). The sabellariids occur in densities as many as 15,000–60,000 individuals/m<sup>2</sup> and are known to have life spans as long as 10½ years (Kirtley, 1994). Aggregations of sabellariid worms create geological formations called worm reefs (Main and Nelson, 1988) and have been reported from around the globe, including Europe (Kirtley, 1992; Naylor and Viles, 2000), Taiwan (Chen and Dai, 2009), Hawaii (Pandolfi et al., 1998), Fiji (Bailey-Brock et al., 2009), etc.

## Summary and conclusion

Coral reef environments host many organisms that actively precipitate mineral matter, encrust or bind sedimentary particles together. The binding organisms of modern reefal ecosystems are critically important as they contribute calcium carbonates to the reef framework, bind particles and rubble and thus stabilize the substrate, and

promote larval recruits and offer food and nutrients as well as habitats for other species such as bacteria, algae, and foraminifera. The most important encrusting organisms of modern reefs are the light-dependent calcareous coralline algae, but many other calcareous encrusting organisms exist including polychaetes, phoronid worms, chaetognaths, holothurians, chordates, foraminifera, corals, bivalves, algae, and bryozoans. These organisms bind sedimentary particles to create a living framework or shelter or the binding process is purely a by-product of the organisms' digestion and scavenging of the sedimentary environment for food.

## BIOEROSION

---

Pat Hutchings  
Australian Museum, NSW, Sydney, Australia

## Definition

Bioerosion can be defined as the destruction and removal of consolidated mineral or lithic substrate by the direct action of organisms (Neumann, 1966) and is complemented by physical and chemical processes of erosion. This review deals only with the removal of substrate from coral reefs and concentrates on modern day reefs. However, there

is an extensive literature on boring organisms on fossil reefs, for a review see Tapanila (2008) and the agents and mechanisms of boring seem similar on these reefs to those occurring on modern day reefs (Wood, 1999).

## Introduction

Bioerosion is a natural process occurring on all reefs although rates and agents may vary across the reef and together with reef growth which also varies, results in them being dynamic systems. It is the balance between these two processes which determines the overall shape of the reef together with physical and chemical erosion of the coral substrate. Bioerosion includes the removal of surface substrate by grazing organism (*Acanthaster planci*; *Sponges*) and the loss of substrate by boring organisms which produces a continual supply of lagoonal and inter-reefal sediments. While reef growth has been well studied (Barnes and Chalker, 1990), bioerosion has been relatively poorly studied. Although this situation is likely to be rectified, as reefs are increasingly being impacted by anthropogenic effects, which often results in changes in the balance between rates of reef growth and reef destruction, with the latter far exceeding reef growth in many parts of the world (Pari et al., 2002; Sheppard et al., 2002). This loss of substrate may have severe biological, economic, and social consequences each of which will be discussed later.

A wide range of organisms are capable of boring into coral substrate and this includes both macro and microborers with recruitment via pelagic larvae or propagules (McCloskey, 1970). Reef building corals have a thin veneer of living coral polyps over the coral skeleton, and these are active carnivores and can capture any larvae of borers which settle on them using their nematocysts. Larvae can also become trapped in the ciliary feeding currents generated by the polyps and carried to the mouth and eaten. This ensures that few larvae settle on live polyps, instead they settle on damaged polyps or any dead areas of the colony or at the base of the colony where typically there is no veneer of living coral. However, once the colony dies, for example, as a result of disease (Sussman et al., 2008), bleaching (Pratchett et al., 2008), predation by Crown of Thorns starfish (*Acanthaster planci*) (DeVantier and Done, 2007), the gastropod mollusc *Drupella* spp., (Morton and Blackmore, 2009), or by other coral predators (Rotjan, and Lewis, 2008), or from the effects of storms (López-Victoria and Zea, 2004), the substrate is rapidly colonized by microborers which conditions the surface and facilitates recruitment of a suite of macroborers.

## Microborers

### Components and processes

A diverse array of micro-organisms colonize coral substrates including cyanobacteria, algae, and fungi; for a review of their taxonomy, see Kobluk and Kahle (1977) and for a review of their boring activity, see Tribollet

(2008). They consist of boring autotrophic and heterotrophic microorganisms or euendoliths (boring microflora) which actively penetrate (biochemical dissolution) the coral substrate (Golubic et al., 1981). Species composition of these communities varies between live and dead substrates. The species composition of those occurring in live coral is positively phototrophic, fast growing taxa which can keep up with accretion of the coral, and can stay in the surface layers of the substrate to obtain sufficient light for their growth (Tribollet and Payri, 2001). One species of chlorophyte *Ostreobium quekettii* Bornet and Flahault, 1899, has been recorded widely from Atlantic and Pacific corals but this may represent a suite of cryptic species (pers. comm. H. Verbruggen as cited in Tribollet, 2008). These algae form a distinct green band just below the coral surface (Figure 1a). Infestation occurs as the coral polyp is settling on the substrate and beginning to lay down a coral skeleton. The same suite of microborers also colonize encrusting coralline algae growing over dead coral substrates. Following death of the coral colony another suite of algae colonize the substrate within a few days (Hutchings, 1986; Gektidis, 1999) (Figure 1b). Early colonists are short-lived opportunistic species. Within 6–12 months, these endolithic algal communities become dominated by low-light specialists and heterotrophic fungi, and are referred to as “mature communities” (Tribollet, 2007). Such changes in species composition are driven by reduced light penetration as the surface of the substrate becomes covered with epilithic organisms, which reduces the amount of light able to penetrate into the substrate and therefore species which can utilize these lower levels flourish. The species composition of the epilithic biota strongly influences which species of boring microflora (euendoliths) are present. For example, under turf algae (Figure 1b) growing on dead *Porites*, colonies of the cyanobacteria *Mastigocoleus testarum* are abundant, whereas a different suite occurs under crustose coralline algae (Chazottes et al., 2002). Substrates in turbid areas may be covered with sediment which inhibits or reduces the density of boring microflora (Osorno et al., 2005).

### Method by which microborers bore

It was thought that the boring microflora penetrated the substrate by dissolving its crystalline matrix (Tudhope and Risk, 1985), but recent studies suggest that there is a temporal separation between photosynthesis and boring activities (Garcia-Pichel, 2006). This involves active transport of  $\text{Ca}^{2+}$  from the apical cell of the filaments to their trailing end occurs which would make dissolution of the substrate around the apical cell feasible when interstitial pH is high due to photosynthesis. This may explain why micrite and brucite are commonly seen precipitated around the microflora filaments at the surface of dead substrates (Kobluk and Risk, 1977). But more studies are required and it may be that the process of substrate dissolution varies depending on the taxa, type of substrate, and environmental conditions (Tribollet, 2008).

## Macroborers

### Polychaetes

#### *Diversity of polychaetes*

Representatives of a variety of polychaete families are found, including Eunicidae, Sabellidae, Spionidae, and Cirratulidae, which are not closely related, suggesting that the ability to bore into coral substrate has arisen several times. Even within a genus not all members are borers. In the Indo-Pacific, some species have been reported as having wide distributions, such as *Nematonereis unicornis* and *Lysidice collaris*, but this needs to be carefully checked using both morphological and molecular data. Information on the boring species present in the Caribbean is lacking. Boring polychaetes are primarily found in dead coral substrate, when they occur in live coral typically a few polyps have been damaged which presumably allows the larvae to settle and penetrate. The only exception to this appears to be a species of Flabelligeridae which is common in some live coral colonies in Hong Kong Harbour (Hutchings, pers. observ.).

#### *Succession of polychaetes*

The first suite of macroborers to arrive are short-lived polychaetes such as species of *Polydora* (Spionidae) and Fabriciiniids (Sabellidae), which can be extremely abundant. These species are either deposit or filter feeders which feed on the sediment trapped in the irregularities of the surface of the substrate or spread their feeding crowns out into the water column above the surface where they filter out food particles. Obviously these species are susceptible to being removed when parrotfishes or echinoids graze on the substrate as they live in the surface layers. Over the next year or so, other boring organisms recruit to these substrates including a range of other longer lived polychaetes belonging to the families Cirratulidae, Eunicidae and Sabellidae (Hutchings et al., 1992; Pari et al., 1998, 2002) which exhibit a range of feeding strategies including surface deposit feeders, filter feeders and others are predators. One suspects that the predators feed on the other macroborers but some may be more opportunistic and also feed on the microborers.

#### *Recruitment of polychaetes*

Following successful colonization of newly available substrates by a suite of endolithic algae, viruses etc. and turf algae, pelagic larvae of boring polychaetes settle on the surface and turf algae may provide some protection for these larvae from small scale water movement which could wash them off the substrate as they metamorphose and begin to bore. Observations on experimental substrates suggest that larvae tend to settle in small depressions (Hutchings, pers. observ.). High rates of mortality of such larvae must occur at this time, but experimental studies have shown that some recruitment of this initial suite of polychaete macroborers occurs throughout the year and to all habitats (Hutchings et al., 1992; Kiene and

**Bioerosion, Figure 1** (a) Endolithic algae inhabit the skeletons of corals, living amongst the crystals and over time weakening the skeleton. (b) Dead coral substratum covered by turf algae (photo: O. Hoegh-Guldberg). (c) In situ dead coral habitat split open to reveal boring sipunculans and bivalves, burrow of boring bivalve (photo: P. (d) The grazing echinoid *Echinometra mathaei*, oral surface showing Aristotle's lantern partially protruding from the mouth that it uses to actually scrape off the surface of the coral (photo: A. Miskelly). (e) Diagram of Aristotle's lantern (Illustration after Anderson, 1996). (f) *Diadema setosum* a grazing echinoid linked to major erosion of western Indian Ocean reefs (photo: O. Hoegh-Guldberg). (g) *Echinostrephus* sp., sitting in its home scar that it has eroded (photo: O. Hoegh-Guldberg).

Hutchings, 1994a, b). However, maximum recruitment of this suite of polychaetes occurs during early summer (Hutchings and Murray, 1982) and significant variations occur between sites on a reef, with maximum recruitment of most species occurring on windward and reef flat sites, and least to a lagoonal patch reef (Hutchings et al., 1992). Studies over several years have shown that as well as seasonal and temporal variation there are also variations between years, and it is suggested that local weather patterns are critical in the dispersal of these larvae (Hutchings et al., 1992). Once the polychaetes are established within the substrate they must retain an opening to the exterior through which they obtain oxygenated water and their food, discharge their waste products and gametes. The only exception to this are some of the eunicids which develop modified back ends full of gametes which become detached from the rest of the body and leave the burrow and swim up into the water column to spawn on particular nights of the year. The most famous being the Palolo worm (*Eunice viridis*) (Caspers, 1984). So basically once the polychaetes have burrowed into the substrate they are effectively entombed and never leave except for some of the eunicids and then only posterior segments.

In addition to recruitment via pelagic larvae, members of the genus *Dodecaeria* (F. Cirratulidae) can also undergo asexual reproduction by splitting into individual segments and with each segment developing a new head and tail, and so inside the burrow an entire family group may be found.

#### *Mechanisms of boring by polychaetes*

Polychaetes bore into the substrate using either chemical secretion to dissolve the reef framework or perhaps mechanically grind the substrate or use a combination of these methods (Hutchings, 2008) but the precise details still need to be worked out. Some of the boring polychaetes such as sabellids and cirratulids must dissolve the substrate as they lack any structures with which to mechanically bore, and sabellids at least have well developed glandular areas at the base of the crown which may be responsible for secreting chemicals which dissolve the substrate. Other groups such as *Polydora* spp. (F. Spionidae) have thickened chaetae on segment 5, and it has been suggested that they can use these to grind the substrate. However, removal of these modified chaetae did not impede the burrowing capacity of *Polydora websteri* (Haigler, 1969). The same species boring into mollusc shells secretes a viscous fluid which dissolves the organic matrices of the shell and subsequently dissolves the exposed crystals (Zottoli and Carricker, 1974), but the chemical composition of this fluid was not determined. More recently it has been suggested that this fluid is secreted all along the body of the worm (Sato-Okushi and Okoshi, 1993) and presumably a similar fluid is secreted by other species which bore into coral substrate. Examination of the walls of the burrows of eunicids reveals bite marks which match the size of their well-developed jaws. Burrows of the larger polychaetes are

distinctive and can be recognized in sections of substrate and those of *Notaulux* (F. Sabellidae) are lined with a fine chitinous tube (Hutchings, 2008). Identifying the burrows of the smaller early recruiting polychaete species is far more difficult as their dimensions are similar to the porosity of the coral substrate.

## Molluscs

#### *Diversity of molluscs*

Representatives of six bivalve families are known to bore into coral (Figure 1c). Of these the Petricolidae, Pholadidae, and Clavagellidae are represented only by a few species and generally bore into dead coral substrate. Species of the Lithophaginae and the Gastrochaenidae play a major role in bioerosion of dead coral with the latter family the dominant one in both the Pacific and the Caribbean. Another suite of species bore into living coral belonging to the Mytilidae and some genera of Lithophaginae. Within *Lithophaga* some species are capable of living in a wide range of coral species, whereas others are restricted to a single species. Species of *Leptoconchus* and *Magilopsis* belonging to the gastropod family Coralliophilidae bore into living coral (Soliman, 1969).

The Indo-Pacific and Atlantic coral reef faunas are quite different, with only 7% overlap at the generic level but none at the species level, 24 genera have been recorded from the Atlantic and 87 in the Indo-Pacific. The genera which overlap are those containing species of the less specialized dead coral borers, and the other genera including those which bore into live coral evolved as the corals themselves diversified (Rosen, 1984). For more information on the evolution of boring bivalves and a detailed list of the coral species bored by particular species of bivalves see Morton (1990).

#### *Succession of molluscs*

Experimental substrates have rarely been exposed for long enough to demonstrate if any succession of species occurs as the dead substrate ages. Obviously as the surface of the dead substrate is eroded the bivalve has to continue to bore deeper in the habitat whereas those boring into live coral must reverse their direction of their boring as the coral grows upwards enlarging its burrow posteriorly to keep the entrance above open, and in these lithophagids, posterior pallial glands secrete an active chelating agent (Morton, 1990).

#### *Recruitment of molluscs*

Bivalves recruit via pelagic larvae, and Morton (1990) suggests that those recruiting to dead coral substrate are similar to other bivalve larvae in their ability to find a suitable substrate on which to settle and bore. Whereas larvae of species recruiting to live corals have to have special adaptations. It appears that larvae settling inadvertently onto a coral species, which they do not normally bore into, are stung by the coral nematocysts and rapidly withdraw their feet. Whereas larvae settling on a coral species which

they are found to bore into, can stay on the surface of the coral for days until they settle and bore into the coral. Scott (1988) found that the larvae enter the coral via the coelenteron and she suggests that they then undergo metamorphosis and eventually bore through the walls into the skeleton although she did not actually observe this. This suggests that the larvae have morphological and behavioral specializations so as to select their specific coral species host and to penetrate its defences.

#### *Mechanism of boring by molluscs*

Many early studies (e.g., Yonge, 1963; Soliman, 1971) suggested that boring in bivalves was largely mechanical but more recent studies of species of Lithophaginae, Pholadidae, and Tridacnidae which bore into live coral suggest that they are chemical borers, with acid-like secretions being produced by the mantle folds. In the species of Lithophaginae which bore into dead coral, calcium carbonate is used to smooth and fill the boring anteriorly. In those more specialized species which bore into live coral the calcium is used to smooth and fill the boring posteriorly and to form secondary extensions to the shell for predator defence. The secretions are produced in this group by pallial glands located in the middle folds of the mantle of lithophagids and in other groups the boring glands are in the inner folds around the pedal gape. Morton (1990) provides more details on selected species across the families as well as details of the structure of the tubes which can be easily assigned to particular species. Detailed descriptions and illustrations of some boring bivalves from the Maldivian coral reefs are given by Kleeman (2008). Morton (1990) suggests that in live coral borers over geological time have evolved from mechanically boring ancestors toward chemical erosion and selective relining of the burrow so that the occupant fits snugly within it.

Bivalves living in live coral have glands on their siphons which secrete a substance which either inhibits nematocyst discharge or protects the siphons from them. Species living in dead coral do not possess these glands (Morton and Scott, 1980). But all boring species living in either dead or live coral need to protect their siphons from predation by predatory animals moving over the surface of the substrate. Some species decorate the openings of the siphon with detrital fragments, others can retract their siphons back down the neck of the burrow and other species protect the posterior edges of the shells valves to help minimize predation. For more details see Morton (1990).

#### *Fossil record of molluscs*

Boring bivalves are well represented in the fossil record, and some of these ancient bivalves are almost certainly ancestors of modern borers, they were uniformly circumtropical in distribution and primarily borers of dead coral. Only in recent times with the evolution of modern coral reefs was the close relationship between boring bivalves and live coral really established, together with the strong separation of Atlantic and Indo-Pacific fauna.

## Sipunculans

### *Diversity of sipunculans*

A number of species bore into coral reef substrates and coral rubble representing several genera. In a study of the distribution of sipunculans at Carrie Bow Cay, Belize, Rice, and Macintyre (1982) found eight species, of which six inhabited burrows within the coral substrate and two which were found on crevices and crannies. Several genera were represented including *Lithacrosiphon*, *Aspidosiphon*, *Paraspidosiphon*, and *Phascolosoma*. Similar genera were recorded from coral substrates in French Polynesia with some additional ones, but they were not all identified to species (Hutchings and Peyrot-Clausade, 2002). Eight species were recorded from studies along a transect in North Queensland, and two species were shared between the Caribbean and the Great Barrier Reef, *Paraspidosiphon steenstrupii* and *Phascolosoma perlucens* (Osomo et al., 2005) (Figure 1c). As with the polychaetes, the habit of boring appears to have arisen independently in several families of sipunculans and the so called widely distributed species need to be carefully checked using morphological and molecular techniques.

### *Succession of sipunculans*

Rice and Macintyre (1982), working in Belize, found that sipunculan density was greatest in relatively unaltered coral substrate which had relatively little secondary infill of calcite cement and that the corals with uniform skeletal framework like *Porites* and *Acropora* were favoured. They found that highly eroded rocks of coral substrate contained few if any sipunculans. Experimental studies have clearly shown that sipunculans do not appear initially but have not revealed any distinct patterns of succession, only that individuals increase with size with increasing exposure (Hutchings and Peyrot-Clausade, 2002).

### *Recruitment of sipunculans*

Rice and Macintyre (1982) have shown that the species of sipunculans which recruit depends on the time of year as individual species have different breeding seasons. On the Great Barrier Reef, Hutchings et al. (1992) found that sipunculans exhibited spatial and temporal variations in recruitment, with some years better than others, and that recruitment was almost totally restricted to summer months, suggesting that breeding occurs at this time, although no information on their breeding cycles is available for these species on the Great Barrier Reef. They were found to prefer reef front situations on the Great Barrier Reef (Kiene and Hutchings, 1994a, b) which supports Rice and Macintyre's (1982) findings from the Caribbean that sipunculans occur in greatest abundance in high-energy reef crest areas, which is contrary to the findings of Bromley (1978) who found that low-energy lagoonal situations in this region were preferred. No other information is available on other factors which may determine species composition or abundances. Peyrot-Clausade and Hutchings (2002) found differences in species composition and

densities between sites, with high island sites being favored over atoll sites, but no clear relationships were seen with regards to water quality, in part due perhaps to relatively low numbers of recruits to all sites over the 5 years of the experiment. Another reason may have been that all these sites had similar depths and exposure, two factors which Rice and Macintyre (1982) suggest are important in determining distributions of this group.

Sipunculans are rarely found in coral substrates which are not covered with algae and epifauna and this is probably because boring sipunculans feed on debris and sand trapped in biota. They do not occur in the living portions of the coral colonies (Rice and Macintyre, 1982).

While most sipunculans recruit by pelagic larvae, *Aspidosiphon brocki* is known to reproduce asexually as well by constricting the posterior end to form a new individual which is then retained in the burrow (Rice, 1970).

#### *Mechanism of boring by sipunculans*

Rice and Macintyre (1972) investigated sipunculan burrows using thin sections and studied three species; and they found fine carbonate skeletal grains in the walls of most burrows examined suggesting that some mechanical abrasion has occurred during the formation of them. However, this skeletal material was not always identical to the framework in which the burrow was created, and they postulate that that it was debris associated with sponge boring on the walls of the burrow, or debris which had fallen into the burrow or internal sediment infill which was present before the sipunculan began to bore. They did find evidence of chemical dissolution as some of the coralline algal fragments and lithified internal sediment was different to the walls of some burrows. However, not all burrows exhibited these changes and they concluded that both mechanical abrasion and chemical action are involved in burrow formation. Warne (1975) concurs with this and he suggests that the variety of hooks, spines, or papillae embedded in the leathery skin of sipunculans may anchor the worm while they are boring into the substrate and perhaps aid in the mechanical grinding of acid softened substrate (Warne, 1975). Their borings are variable, most are simple, blind, straight to gently curved or sometimes highly sinuous tubes, containing a single specimen (Rice, 1969; Rice and Macintyre, 1972).

#### *Fossil data for sipunculans*

Fossil sipunculans have been recorded from the Burgess Shale, although some workers have disputed this, but no records from fossil reefs could be found.

### Sponges

#### *Diversity of sponges*

The following Orders of sponges include bioeroders, Hadromerida (Clionidae, perhaps Spirastrellidae, and the Alecionidae), the Poecilosclerida (Acanthidae, i.e., the genus *Zyzya*), the Halichondrida (Halichondriidae, i.e., the genus *Amorphinopsis*), and the Haplosclerida (Phloeodictyidae, i.e., the genus *Aka*) and there are a few “maybe eroders”

in other Orders (Hooper and van Soest, 2002; Schönberg, pers. comm.). This suggests that the ability to bioerode has developed several times within the Porifera.

The taxonomy of sponges is currently undergoing major revisions as many of the so called “cosmopolitan” species are being described as suites of new species based on molecular data, even though it is difficult to separate them morphologically (Xavier et al., in press). Ongoing revisions of bioeroding sponges indicate that they are more diverse in the Indo-Pacific (Schönberg, pers. comm.) than in the Atlantic even though the Atlantic communities are far better studied (e.g., Rosell and Uriz, 1997). A phylogenetic study of the genus *Cliona* has clearly shown that it is polyphyletic group but Rosell and Uriz (1997) preferred to maintain the genus until more detailed information was available on a wider range of taxa within this group.

#### *Succession of sponges*

While no data appears to exist on possible succession of species in coral substrates over time, there has been a widely held view that species may exhibit various growth forms with age. It has been suggested that there is an initial alpha (=papillate), later beta (=encrusting), and then a gamma-massive free living morphology (Hartman, 1958). However, Schönberg (2008) does suggest that as no single species has ever been followed from settlement to the free living form, and not all growth forms are found within a single habitat, and as most species are known only as alpha-papillate forms, it may be that different growth forms represent different species. However, Rützler (pers. comm.) disputes this and suggest that some gamma stages have been wrongly linked to certain alpha stages (e.g., *Cliona nigrescens* to *C. viridis*, in the Mediterranean). This apparent ability of some species to exhibit different growth forms could be very useful for taxonomy together with molecular data which is increasingly being used to separate species.

#### *Recruitment of sponges*

Recruitment is via pelagic larvae, but information on seasonality is not available. The clionaid sponges, one of the dominant boring groups, are found in both dead and live coral as their larvae have the ability to survive direct contact with coral polyps, but their ecological success at invading coral substrates is largely due to their ability to undermine and erode the coral skeletal base which is typically dead, thus avoiding contact with the defensive mucus and nematocysts of the coral polyp.

López-Victoria and Zea (2004) working in the Caribbean found that sponge bored fragments of coral could be redistributed across the reef and infect new coral fragments. This method of colonization can result in rapid build up of populations and may occur often after storm events.

#### *Mechanism of boring by sponges*

Detailed studies have been undertaken on the way in which sponges bore (Rützler and Rieger 1973; Pomponi,

1977, 1979a, b, and the history of sponge boring studies has been reviewed extensively by Schönberg (2008). Sponge erosion involves chemical etching of the substrate producing cup-shaped fissures and the mechanical removal of the resultant sponge chips through the sponge oscula and carried away by water currents (Neumann, 1966; Rützler and Rieger, 1973; Hatch, 1980). The etching agents are produced by specialized etching cells with filopodia which allows very localized application of the agents and enzymes. Pomponi (1977, 1979a, b) undertook detailed studies on the ultrastructure of these etching cells and she suggests that they are capable of protein synthesis, absorption, and intracellular digestion. She also found that carbonic anhydrase activity was associated with etching cell bodies, their filopodia and the spaces between them, whereas acid phosphatase activity was most intense on the outer surfaces of the cell processes but also detectable in the cell organelles. She argued that phosphatase was involved in the extra- and intracellular digestion of the organic compounds of the substrate, and carbonic anhydrase in the dissolution of the mineral components (Pomponi, 1980). Hatch (1980) was the first worker to provide the biochemical evidence to support the shifting of the carbonate equilibrium and he discusses how substrate dissolution may occur. Although Rützler and Rieger (1973) suggest that only 2–3% of the eroded substrate is chemically dissolved and the remaining removed mechanically, recent studies by Zundevich et al. (2007) suggest that far more is removed by chemical dissolution but Schönberg (2008) questions this. It may be that this ratio varies according to the group and may shift with changing environments (e.g., with ocean acidification).

Sponge boring produces characteristic traces, which are called “chambers” in the substrate which often end in minute pioneering ducts. The macroscopic patterns of chamber size and distribution have traditionally been used for taxonomic purposes (e.g., Rützler, 1974) or for measuring rates of boring (Rose and Risk, 1985). However, it has been clearly shown that a species can produce more than one kind of trace, a single trace may have been produced by several sponge species (Bromley and D’Alessandro, 1989), and these are influenced by many environmental factors, such as substrate density, water flow, and quality (Schönberg 2008). Boring also produces sponge chips which are dislodged mechanically and then transported out of the sponge galleries. These chips have characteristic shapes and morphologies which can be easily recognized in sediments, including lagoonal, inter reefal areas, concretions within previously bored substrates, etc.

Species determination can be difficult and chip dimensions have been used with some success to separate species, but sponge chip and sponge scar dimensions vary within the substrate whereas genera can be differentiated based on spicule shapes.

They tend to be larger in central established regions of the sponge boring, and with smaller diameters in pioneer regions (Rützler and Rieger, 1973). They also vary with

substrate type. Calcinai et al. (2008) working on a species of *Cliona* found that while microsculpturing of scars was similar in different substrates, other microscopic and macroscopic traces varied with substrate. They suggest this is due to the substrate microtexture.

#### *Rates of boring*

Variations in rates of boring by sponges experimentally (Bak, 1976 and references therein) suggest that rates vary according to species of sponge, substrate density (Highsmith et al., 1983; Rose and Risk, 1985; Edinger and Risk, 1997), location and depth (López-Victoria and Zea, 2005) on the reef. More material is removed from massive corals with less porous skeletons than from less massive more porous species (Buddemeier et al., 1974) and this has also been observed for the other macroborers (Hutchings, pers. observ.). Based on field observations from many geographical locations and experimental studies, other factors are also important in determining rates and abundances of boring sponges such as water flow (López-Victoria and Zea, 2005); nutrient or sewage concentration (Hutchings et al., 2005; Holmes, 2000; Holmes et al., 2000); temperature with rates in the Red Sea varying with season, and being lower in cooler areas (Mokady et al., 1993; Zundevich et al., 2007); and light especially if the sponge has symbiotic algae (López-Victoria and Zea, 2005). On impacted reefs, where many species are under stress, boring sponges thrive (Rützler, 2002; Márquez et al., 2006). Finally, rates are not constant over time with larvae or fragments freshly settling or attaching, having higher rates of growth and erosion; in contrast established colonies exhibit slow growth and low rates of erosion (Neumann, 1966; Rützler, 1975).

#### *Habitat modification by sponges*

Sponges are important in modifying habitats through bioerosion, and often physically support corals, preventing collapse after their basal structure has been eroded (Goreau and Hartman, 1963). They are also important in reef framework consolidation as they hold corals and rubble together during sediment infilling and lithification (see Wilkinson, 1983, for more details). Encrusting species of boring sponges can overgrow neighboring corals (López-Victoria and Zea, 2004; López-Victoria et al., 2006) and kill the corals.

#### *Sponges in the fossil record*

Sponges were among the first metazoans to occur in the geological records. The first reefs that were constructed primarily by sponges were in the late Ordovician period, where sponges had massive, fused, calcareous skeletons, the Stromatoporidae (Wilkinson, 1983). Kobluk and van Soest (1989) suggest that as sponges have limited preservable skeletal material, the fossil record on later reefs may be a poor representation of their importance in fossil reef systems, although the burrows would still be apparent.

## Succession of macroborer communities

Experimental studies have clearly demonstrated that a distinct succession of macroborers occurs, initially certain species of polychaetes (Hutchings and Murray, 1982) with some recruitment occurring regardless of when the substrate becomes available. A few sipunculans begin to colonize after 6 months (Davies and Hutchings, 1983; Hutchings and Peyrot-Clausade, 2002) and later on bivalve molluscs and sponges are found (Kiene and Hutchings, 1994a, b; Pari et al., 2002; Osorno et al., 2005). No studies either on the Great Barrier Reef or in French Polynesia have ever found sipunculans, molluscs, or sponges until newly available substrates have been exposed for at least 6 months, and in many cases sponges did not appear until after 4 years of exposure (Kiene and Hutchings, 1994b; Pari et al., 2002). Experimental studies have shown significant variations in recruitment patterns across a reef and within geographical areas (Kiene and Hutchings, 1994a, b; Osorno et al., 2005; Pari et al., 2002). However, these studies have usually been carried out over 2–5 years, with only one study extending for 7 and 9 years (Kiene and Hutchings, 1994a). They contrast with the “mature” communities which have well developed sponge borings, numerous large bivalves, with polychaetes restricted to large eunicids and sabellids, and these have developed over decades, rather than the few years over which experimental studies have been conducted. It is these “mature” communities which have been typically described in the literature (Neumann, 1966; Hein and Risk, 1975; Hudson, 1977; MacGeachy, 1977; Risk and MacGeachy, 1987; Davies 1983).

All these macroborers which have characteristic shaped burrows must maintain an opening to the outside to obtain a continual supply of fresh oxygenated water, food supply and for the release of excretory and reproductive products, but they cannot leave the substrate as they are effectively entombed within it. Examination of many cut surfaces clearly shows that burrows of different organisms rarely if ever touch or coalesce and presumably boring creates vibrations to which other borers are sensitive and allows them to take the necessary avoiding action.

## Grazers

### Echinoids

In the Indo-Pacific the main grazing species belong to the following genera, *Diadema* (Figure 1f), *Stomopneustes*, *Echinothrix*, *Echinostrephus* (Figure 1g), and *Echinometra*, with *D. savigny* and *Echinometra mathaei* (Figure 1d) often being the two most conspicuous species. In the Caribbean, the two most common species are *Diadema antillarum* and *Echinometra viridis*, so while these genera are also present in the Indo-Pacific, different species are present.

### Method of grazing

Echinoids use their Aristotle's lantern specialized plates of the mouth (Figure 1e) to grind the coral substrate into a paste which is then swallowed and the contents of the

ruptured algal cells are then absorbed by the gut. Such grazing occurs mainly at night with the echinoids leaving their crevices and roaming over the reef and fresh feeding scars can be seen in the morning (Figure 1g). Faecal pellets produced, consist almost entirely of ground up calcium carbonate and these are deposited on the substrate or on the lagoon floor.

### Rates of grazing

Rates of bioerosion by *E. mathaei* have been estimated at  $6.9 \pm 2.2 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$  in French Polynesia at Faavaa, Tahiti, a very degraded reef where overfishing has occurred, lower rates were found at nearby Moorea of  $4.3 \pm 3.6 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$  (Figure 4). Rates of  $8.3 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$  were estimated for the reef flat at Reunion, Indian Ocean (Peyrot-Clausade et al., 2000) and similar rates were recorded at Diani reef in Kenya (McClanahan and Muthiga, 1988), both of these reefs have also been subjected to overfishing. In the Caribbean on degraded reefs, rates of grazing by echinoids can exceed  $22 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$  (Glynn, 1988; Reaka-Kudla et al., 1996) where the dominant species is *Eucidaris thouarsii*. On the Great Barrier Reef, Australia, densities of grazing echinoids are very low (Sammarco, 1985) and this may be in part due to healthy fish populations which predate on juvenile echinoids. While echinoids have typically been regarded as grazers feeding on endolithic algae, some species of the family Echinometridae are active borers especially in high energy situations (Asgaard and Bromley, 2008). For example, *Echinometra lucunte* which occurs in the Caribbean and the Atlantic produces cup-shaped burrows as juveniles and it is suggested that these burrows enable the echinoid to catch drift algae with their spines, as well as grazing on the turf and endolithic algae on the walls of the burrow. Adults tend to occupy elongated grooves and presumably both types of burrows provide shelter from wave action and the species tends to stay within the confines of their burrow. A similar behaviour is exhibited by *Echinometra mathaei* in the Western Pacific especially in the high-energy environments outside barrier reefs, although they do leave their burrow at night especially in a lagoonal situation (Peyrot-Clausade et al., 2000). Details about the other echinometrid echinoids are given by Asgaard and Bromley (2008) together with some excellent illustrations of the various species and their burrows and they summarize all the information that is available on each species and provide rates of grazing where known.

### Echinoids in the fossil record

Similar genera of grazing echinoids have been recorded from fossil reefs although as Greenstein (1993) explains they are not well conserved as their fragile skeletons do not preserve well so that abundances may be severely underestimated.

### Molluscs

A high diversity of gastropods and a lower diversity of chitons occur on reefs, with distinct faunas in the Indo-Pacific and Atlantic.

### Method of grazing

Gastropod molluscs and chitons can be responsible for considerable losses of substrate on intertidal reefs. They use their radulae to remove the surface layers and the embedded endolithic algae and like the parrotfishes and echinoids they are able to break down the algal walls and utilize the contents of the plant cells. Chitons excavate a home scar to which they return to, after foraging, mainly at night during low tide. They may be locally abundant on intertidal reef flats.

### Rates of grazing

A recent study at One Tree Island, Great Barrier Reef based on *Acanthopleura gemmata*, estimated rates of erosion of 0.013–0.25 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> at two sites on the reef margin and on the beachrock platform (Barbosa et al., 2008) (Figure 2a). While these figures are much lower than those for echinoids and scarids they can be very important in some habitats.

### Grazing on live corals

The gastropod *Drupella* feeds on live coral (Shafir et al., 2008; Lam et al., 2007) as does the Crown of Thorns Starfish (*Acanthaster planci*) (DeVantier and Done, 2007 and references therein) and the resultant dead coral then becomes available for colonization by borers. Gastropods belonging to the genus *Duprella* are obligate corallivores and specialize on acroporid coral especially *Acropora* and *Montipora* spp. (Morton et al., 2002). Recently large colonies of *Platygyra acuta* and *Platygyra carnosus* were observed in Hong Kong to be severely eroded at their bases which makes them very susceptible to storm damage. This erosion was caused by the gastropod *Drupella rugosa* which was feeding on the living coral tissue and then by grazing of the newly available substrate which had been colonized by endolithic algae by the echinoid *Diadema setosum* (Lam et al., 2007). A recent review by Morton and Blackmore (2009) suggests that the dense concentrations of *Drupella rugosa* and another corallivorous gastropod *Cronia margaritcola* regularly seen in Hong Kong Harbour are not plagues but rather breeding aggregations and they actually doubt that these gastropods pose a threat to the corals, contrary to the findings of Lam et al. (2007). However, there are well-documented cases in which localized population outbreaks of *Drupella* spp., as well as the starfish, *Acanthaster planci* and can rapidly and severely reduce the percentage cover of live coral, although some reefs subsequently recover (Glynn, 1973; Colgan, 1987).

### Parrotfishes

The Scaridae, a family of labroid fish, are highly characteristic of coral reef habitats. With few exceptions their geographical distribution is linked to tropical reef environments. Compared to other tropical perciform fish, their diversity on the reef is not that great, with about 25 described from the Great Barrier Reef (Choat and Randal, 1986). While some of these have Indo-Pacific distributions others have

restricted ranges. In the Caribbean, 15 species are present, and those in the genera *Cryptotomus*, *Nicholsina*, and *Sparisoma* are restricted to this area. The genus *Scarus* is the dominant Indo-Pacific genus and there are six species in the Caribbean that appear to be fairly recent colonizers; *Sparisoma* has been there for much of the Tertiary. Only one Caribbean parrot fish *S. viride* has the capacity to significantly bioerode calcareous substrata compared to several species in the Indo-Pacific (*Bolbometopon muricatum*, *Cetoscarus bicolor*, and the five large species of *Chlorurus*). Additional species occur off the African coast and of Brazil (Choat, pers.comm.).

### Method of grazing

It is the presence of dense colonies of endolithic algae which attracts numerous grazing scarids or parrot fish to both live and dead coral (Figure 2b). Scarids or parrotfish, now regarded as belonging to the Labridae family (Cowman et al., 2009); can be divided based on jaw morphology into excavators which remove pieces of the substrate (Figure 2b) and scrapers (Figure 2e) which have a nonexcavating bite just removing material from the surface of the substrate. Schools of parrotfishes can often be seen and heard feeding in the late afternoon in shallow waters (Figure 2d) and distinctive grazing marks are visible on the surface of both live and dead coral substrates (Figure 2e). While most parrotfishes feed on dead coral substrates the large *Bolbometopon muricatum* has a diet which consists of over 50% of live corals (primarily *Acropora* species, Bellwood, 1986) (Figure 2c). Some others that graze on *Porites* spp., occasionally, include the excavators *Scarus gibbus* and *Cetoscarus bicolor* and the scrapers *Scarus frenatus* and *S. rivulatus* on the Great Barrier Reef, Australia. Such findings are contrary to the traditional view that parrotfishes feed on dead coral substrates and recent studies in the Caribbean have shown that feeding on live coral can also be widespread. A study on the back reef habitat at Carrie Bow Cay, Belize in the Caribbean, found that parrotfish predation on the reef building coral *Porites astreoides* was significant with >13% of colonies exhibiting partial or total colony mortality (Rotjan and Lewis, 2005). A suite of parrotfishes were present but probably the most important species was *Sparisoma viride*. Not only were the fishes targeting the endolithic algae but in grazed areas of the colonies there were significantly higher densities of macroborers namely barnacles, polychaetes, and vermetids. Rotjan and Lewis (2005) speculate that the parrotfishes were targeting such areas to obtain additional nutritional benefits from these macroborers. Subsequent studies by Rotjan and Lewis (2006) investigated the spatial and temporal patterns of parrotfishes across habitats on the Belize barrier reef. They found that parrotfishes were selective in the live corals on which they grazed. The most heavily targeted species were all members of the *Montastrea annularis* species complex, and colonies of *M. cavernosa*, *Agaricia agaricites*, *Diploria strigosa*, *Porites astreoides*, and *Porites porites* were not heavily targeted. Parrotfishes also

(b) The parrot fish *Scarus* sp. with well developed jaws about to take a lump of dead coral substratum full of endolithic algae (photo: O. Hoegh-Guldberg). (c) Jaws of *Bolbometopon muricatum* on the outer barrier near Lizard I. (photo: D. Bellwood). (d) Schools of *Bolbometopon muricatum* at Osprey Reef, Coral Sea (photo: P. Hutchings). (e) Bite marks of a scarid and a boring barnacle embedded in *Porites lutea* (photo: O. Hoegh-Guldberg). (f) Defaecation by parrotfish, fine sediment produced by the grinding of the ingested coral fragments (photo: D. Bellwood).

exhibited differences in preferred coral species depending upon habitat, with *M. annularis* being preferred in shallow habitats, whereas *M. franksi* was consumed more at depth and *Siderastrea siderea* was preferentially grazed only in the spur and groove habitats. Given that numbers of

*Sparisoma viride* and *Sp. aurofrenatum* increased between 1982 and 2004 on the Belize barrier reef, there would have also been a corresponding increase in grazing on live coral and the impacts of this on coral survival needs to be evaluated (Rotjan and Lewis, 2006).

Once excavating species have bitten off fragments of substrate, the fragments pass into the muscular pharyngeal mill at the beginning of the gut. The mill consists of grinding surfaces covered in teeth which are continuously replaced, and as these surfaces are moved back and forwards the coral fragments are broken down into a fine powder releasing the algae and breaking the plant cells releasing the nutrients which are then absorbed by the fish and the fine powder is released into the water column (Bellwood and Choat, 1990) (Figure 2f). It has been shown that the gut contains the necessary enzymes to breakdown the cellulose plant walls (Choat et al., 2002).

#### *Rates of grazing*

Rates of grazing by parrotfishes (Figure 2e) have been estimated from 0.61 to 1.68 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> in Barbados (Frydyl and Stearn, 1978), 0.05 to 0.9 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> at La Réunion, Indian Ocean to 0.7–3.30 CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> at Moorea, French Polynesia (Peyrot-Clausade et al., 2000), 0.9–3.89 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> – on inner reefs, increasing to 5.2–8.4 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> on mid shelf reefs and 32.3 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> on the outer shelf reef crest and 23.1 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup> on the reef flat with very little erosion occurring on the outer shelf reef slope or back reef habitats (0.8–1.8 kg CaCO<sub>3</sub> m<sup>-2</sup> year<sup>-1</sup>) on the Great Barrier Reef (Hoey and Bellwood, 2008). In part this is a reflection of the distribution of grazers across the reef (Russ, 1984) which has been well documented for the Great Barrier Reef. A variety of methods have been used to estimate these rates so that some caution needs to be taken in interpreting these results and obviously rates depend on species, size of individuals, location of study both within and between reefs and methods used. Some workers have measured the amounts of calcium carbonate in the gut (Peyrot-Clausade et al., 2000) whereas others (Bellwood, 1986; Bruggemann et al., 1996; Frydyl and Stearn, 1978; Rotjan and Lewis, 2005, 2006) have measured the size of the bite marks, depth of excavation and observed the frequency of feeding and calculated the amount of substrate removed and factored in size and densities of the fish populations to obtain rates of loss over the reef.

On healthy reefs, bioerosion by parrotfishes is the dominant agent of grazing, and typically loss of substrate by these fishes across the reef tends to be balanced by net calcification (Hoey and Bellwood, 2008).

#### *Evidence of grazing from fossil reefs*

Parrotfishes are well preserved on fossil reefs and the oldest ones including a species of *Bolbometopon*, an eroder are all of Miocene age (Bellwood and Schultz, 1991). Molecular data suggest that the basal parrotfish division into seagrass and reef clades occurred approximately 42 million years ago (Streelman et al., 2002). Although the feeding mode of the reef clade is equivocal, the origin of this lineage at 42 Ma provides an independent estimate of the maximum age of parrotfish bioerosion. The impact of herbivores, therefore, may have had two phases, with a rise in nonexcavating grazing prior to the early

Eocene and the advent of deep excavating fish herbivory sometime later, between 42 and 5 Ma (Bellwood, 2003). Obviously interactions between herbivory and coral reefs have been occurring for a very long time with changes in the composition of the coralline algal crusts of substrates associated with an increase in the density of fish grazers (Bellwood, 2003, Figure 7). Much of this evidence is from analyzing the mouth parts of the fish present in various fossil reefs, as actual bite marks or evidence of grazing are unlikely to have been preserved. More recent molecular studies are confirming these timelines (Read et al., 2006).

#### **Predation on live coral**

A great variety of organisms prey on live coral predators and Rotjan and Lewis (2008) provides a detail list by species (includes both vertebrates and invertebrates) and geographical regions. They distinguish between species which remove only mucus, coral tissue, or skeleton, and they provide rates of consumption reported in the literature, which were based either on the number of bites per minute or the % of live coral in the gut.

All this grazing activity which removes the surface layer of the coral substrate exposes a new surface which is then rapidly recolonized again. Grazers while targeting the endolithic algae also collect any other type of boring organisms living in the surface layers of the coral skeleton (Rotjan and Lewis, 2005).

#### **Determining rates of bioerosion**

Experimental studies have measured rates of bioerosion using blocks of recently killed colonies of *Porites* which have been attached to the substrate for varying lengths of time (Figure 3a). Blocks are then sliced and measured and changes in dimensions determined, to determine loss of substrate by external grazing, increases in dimensions by accretion of coralline algae and losses by internal erosion by macro and microborers (Figure 3b). Rates of loss by borers involve calculating the volume of the burrows and because of their characteristic shapes and sizes they can be apportioned to each of the major groups of borers. By knowing the density of the coral substrate the amount of calcium carbonate lost can be calculated and then figures extrapolated to amounts per m<sup>-2</sup> year<sup>-1</sup> although obviously the distribution of substrate available for colonization is not uniform across a reef. These rates also include loss of substrate by physical and chemical erosion but separating them from losses caused by bioerosion is almost impossible (Peyrot-Clausade et al., 1995). All these processes also act synergistically, for example as the substrate becomes honeycombed by borers this facilitates physical erosion as water is flushed through the substrate, or when pieces of substrate are removed by grazers, new surfaces are exposed facilitating further losses by chemical and physical erosion.

Rates of loss will vary across the reef depending on the amount of live coral cover present as well as the morphological types present (massive, plate, branching, encrusting) and the amount of dead coral substrate of varying ages

**Bioerosion, Figure 3** (a) Experimental study of bioerosion at Osprey Reef, Coral Sea, two replicate grids with newly laid coral blocks to be exposed for varying lengths of time (photo: J. Johnson). (b) Diagrammatic representation of coral block illustrating how the various components of bioerosion (i.e. grazing, accretion and boring) are determined from a series of sections through each block. Knowing the density of the coral block, these measurements can then be scaled up to rates per square metre and then net rates of bioerosion calculated. a, original block; b, accretion; c, block remaining after grazing and boring.

(i.e., time since death of coral colony) present, as rates tend to increase with increasing maturity of boring communities (Peyrot et al., 1992). While most studies on the distribution of boring communities have focused on the massive coral *Porites*, all corals are bored once they die, but dense coral skeletons are most impacted. Comparing rates of bioerosion across or between reefs must be carefully considered as rates vary according to amounts and types of substrate available. Rates will also vary over time as the composition of boring communities change and may stabilize as the component individuals mature. Rates of grazing and accretion may vary over time and sediment may also be washed into the burrows created by the borers, recemented and thus strengthening the substrate, so just comparing rates of bioerosion can be fairly meaningless unless information on all the components contributing to the balance between reef growth and destruction are known.

In addition to calculating rates of loss by internal erosion, it is important to identify the organisms responsible for these losses. The easiest method for extracting the macroborers is to dissolve the substrate in a weak acid solution and sort the residue into the relevant groups and identify to species. However, typically the volume of the macroborers is lower than the loss of substrate calculated from measuring the size of the burrows and this probably is a reflection that some of the borers have established themselves in the substrate and then died during the exposure period but their burrows remain (Pari et al., 2002). Determination of the species composition of the microborers requires a variety of techniques, see Tribollet (2008). Amongst both the micro and macro- borers there appears to be some widely distributed species, however it may be that with more detailed taxonomic investigations involving both morphological and molecular techniques that suites of cryptic species will be found.

Another method of calculating rates of bioerosion is to collect large heads of dead coral of known age, slice them and measure the loss of substrate by internal erosion and extrapolate to losses per  $\text{kg m}^{-2} \text{ year}^{-1}$  (Hudson, 1977). This makes the assumption that rates of boring are

consistent over time but we know that this is not correct and so such methods of estimating rates may be of limited value. Examining such heads of dead coral often reveals that much of the erosion occurs at the base of the colony and this may make the colony more susceptible to being dislodged during storms or when large heads of corals are rolled down the reef slope during a storm clearing everything in its path. Although there are some data to suggest that heavily sponge bored coral heads may be more flexible and able to withstand some storm activity, other data from branching corals indicate the reverse that such colonies are more susceptible to being damaged (López-Victoria and Zea, 2004; Chaves-Fonnegra and Zea, 2007).

### Habitat creators

Bioerosion, as well as generating sediment, which may either be washed out of the substrate and contribute to inter reefal and lagoonal sediments or retained within the burrows and subsequently become cemented, also creates a 3D habitat. The creation of this habitat provides suitable refuges for a wide variety of invertebrates and some of the smaller fish species and is referred to as the cryptofauna or nestlers. This is where the majority of reefal biodiversity and productivity resides and is a critical component of reefal food chains, trapping sediments, and recycling mucus, providing food for many other organisms. While much of the cryptofauna lives permanently within the substrate, some venture out at night to feed or extend their tentacles, arms or feeding crowns, etc., out over the surface of substrate to feed. This fauna cannot themselves bore but they occupy the vacant burrows created by the borers. Some cryptofauna are preyed upon by a range of other organisms, for example, species of the gastropod *Conus* feed selectively on certain species of polychaetes. *Conus* uses its proboscis to suck out these species from within the coral substrate (Kohn and Nybakken, 1975) and some species are highly selective as to which species of polychaetes they prey upon. One presumes that within the substrate the borers and cryptofauna function as an ecosystem

with animals preying upon each other, feeding on the endolithic algae and recycling sediment and mucous trapped within the substrate. A few studies have attempted to quantify the density and diversity of this combined community (Grassle, 1973; Kohn and White, 1977) which is very diverse and abundant although the taxonomy of many of the groups is poorly known. As well as errant species of cryptofauna there are many encrusting species of bryozoans, sponges, and ascidians which utilize these burrows all contributing to the incredible diversity of coral reef invertebrates.

### Environmental factors influencing rates and agents of bioerosion

Studies have shown that rates and agents of bioerosion exhibit spatial and temporal differences (Kiene and Hutchings, 1994b) within a single reefal system, subtidal reef slopes, and lagoonal sites experienced higher rates of grazing than deeper sites and reef flats and these differences were maintained in experimental substrates exposed for 9 years (Kiene and Hutchings, 1994a). These differences could be explained by the distribution of the dominant parrotfish in the region. Many of the boring organism exhibit seasonal variation in recruitment and these patterns are influenced by prevailing winds (Hutchings and Murray, 1982) but storms may modify these patterns transporting larvae to unsuitable habitats.

Experimental studies have also shown that the composition of both the micro and macroboring communities varies not only according to site but to environmental conditions (Hutchings et al., 2005). Inshore sites with heavy sedimentation from river run off are characterized by deposit feeding polychaetes and filter feeding sponges and low densities of endolithic algae are restricted due to light availability which reduced levels of grazing. In contrast communities further offshore in clear waters with little or no sedimentation are characterized by high rates of bioerosion due to grazing and internal bioerosion by macroborers such as bivalves and filter and surface deposit feeding polychaetes (Osorno et al., 2005; Hutchings et al., 2005).

Reefs have always been subjected to storm events and probably plague events such as Crown of Thorns starfish, which leads to a temporary increase in dead coral substrate and local increases in rates of bioerosion, over time these reefs recover providing surrounding reefs are “healthy” (Brodie et al., 2005) and the balance between reef growth and reef destruction is restored. But increasingly this balance is being changed with losses exceeding gains and the next section discusses the factors which are disrupting this balance.

### Anthropogenic factors influencing rates and agents of bioerosion

#### Poor water quality

Experimental studies have shown that rates of microbioerosion and erosion by grazing predominantly

by parrotfishes increased when nutrients are added to the water column (Osorno, 2005). Studies in French Polynesia at selected sites which were subjected to both increased sediment loads and elevated nutrients and significant differences were found between sites some of which were separated by thousands of kilometers. Both eutrophic and pristine sites exhibited high rates of bioerosion although the processes responsible for this loss differed. At the most eutrophic site Faaa, Tahiti, rates of loss were largely due to grazing by echinoids especially *Echinometra mathaei*, whereas at the pristine site at Tikehau, high rates of internal bioerosion were due to sponges (Pari et al., 2002). At Faaa, densities of  $201 \pm 60.4$  indi  $m^{-2}$  of echinoids were recorded (Pari et al., 1998) and an almost complete absence of herbivorous fish especially parrotfishes, due to overfishing. A river flowing out on this lagoonal site at Faaa is highly polluted as untreated sewage and other organic pollutants are allowed to be discharged into this river. These eutrophic conditions allow dense populations of free standing algae and endolithic algae to flourish and which are heavily grazed by the echinoids (Figure 4). This grazing activity together with dense algal cover severely limits the successful recruitment of coral larvae and at this site the balance between reef growth and reef destruction is strongly skewed toward reef destruction. Pari et al. (2002) estimated a loss of reef framework of  $6.87 \pm 2.16$  kg  $m^{-2}$  year $^{-1}$  at this site (Figure 4).

Field studies in the Grand Caymans found a marked increase in the biomass of the boring sponge *Cliona delitrix* in the coral *Montastrea cavernosa* in areas on the fringing reef affected by the discharge of untreated sewage. This resulted in a significant loss of coral skeleton which was reduced to silt-sized sediment and so the proliferation of a bioeroding organism in the sewage-stressed environment has caused a shift in the carbonate balance on the reef (Rose and Risk, 1985). Similar results were found in Indonesia with polluted sites exhibiting higher rates of bioerosion both of live massive corals and

**Bioerosion, Figure 4** Experimental blocks after six months showing extensive grazing by *Echinometra mathaei* at Faaa, Tahiti (photo: M. Peyrot-Clausade).

branching coral rubble compared to relatively unpolluted sites (Holmes et al., 2000).

Studies in the polluted Hong Kong Harbour showed that stressed corals were more extensively bored than healthy ones (Dudgeon and Morton, 1982) and weakened the skeleton making it more susceptible to storm damage. In contrast low densities of mollusc borers in healthy corals may actually strengthen the substrate as *Lithophaga* lines its burrows with aragonitic secretion (Barthel, 1982).

Both experimental and field studies show that while eutrophic sites experience high levels of bioerosion (Reaka-Kudla et al., 1996; Cortes, 1993; Holmes et al., 2000), pristine sites may also exhibit elevated rates (Pari et al., 2002). So high rates per se do not always indicate poor water quality.

### Increasing water temperatures

Sites in the Caribbean with extensive stands of the elkhorn coral *Acropora palmate*, which were subjected to massive mortalities and bleaching during the 1980s, now consist of broken dead stands covered by the encrusting and excavating sponge *Cliona tenuis*. As the sponge undermines the branches of coral, they break off and during storms they are thrown against new coral hosts and the sponge is able to colonize a new uninfected coral colony. The times of initial colonization of the corals by the sponges was related to the timing of hurricanes in the area. In addition to infecting the dead branches, the sponge was also undermining encrusting and foliose corals settling on the dead *A. palmata*, retarding the recovery of these reefs (López-Victoria and Zea, 2004).

Extensive mortality of corals from bleaching at Uva Island, Panama caused by the prolonged 1982–1983 El Niño event, led to significant increases in echinoid grazers and increased rates of internal bioerosion led to significant loss of reef framework and collapse of reef walls (Eakin, 1992).

Kleeman (2008) working on reefs in the Maldives after a severe bleaching event found dense concentration of the bivalve *Parapholas quadrizonata* with boreholes reaching 80 mm in length and 25 mm in diameter and he estimated life spans of 3–8 years probably 10 years. Thus a continual supply of larvae is being produced and as many of the reefs have less than 50% live coral cover following the severe bleaching event in 1998, this has resulted in an accelerated rate of loss of reefal substrate as suitable dead coral substrate is available for colonization by the bivalves (Kleeman, 2008).

### Cumulative impacts

Initially many of these anthropogenic impacts were related to the location of most coral reefs in developing countries with increasing urbanization and declining water quality in part due to lack of sewage treatment works, unregulated coastal development leading to excessive land run off, loss of riparian vegetation along the rivers flowing onto the reefs, overfishing and inappropriate fishing techniques

such as dynamite fishing and collecting of coral for building and inappropriate dredging in lagoons. Typically, this has led to damaged fringing reefs close to centres of population. These same communities were also exploiting the reefs as tourist attractions earning valuable revenue with often the nearby hotel developments also impacting on these reefs. But during the 1980s increasing records of widespread bleaching of coral were being recorded, while some bleached coral colonies recovered many did not. Satellite imaging of surface water temperatures allowed the areas where bleaching was likely to occur to be determined and subsequent surveys often supported these predictions. As well as the duration of elevated water temperatures other factors such as water quality seemed to be involved in determining the recovery of the reef as well as location of nearby unaffected reefs. Increased incidences of bleaching around the world highlighted the impact of climate change on reefs, and it became evident that reefal ecosystems are one of the most vulnerable to climate change. A recent vulnerability assessment of the climate change on the Great Barrier Reef (Johnson and Marshall, 2007) is a sobering analysis of the various aspects of reefs, which are changing, not just elevated temperatures, increased storm intensities, increased run off, increasing alkalinity, rising sea levels, and changes in oceanography which will impact on recruitment processes, increased disease and invasive species, for example. Many of these impacts will result in increased amounts of dead coral substrate and thus higher rates of bioerosion of reef framework (Hutchings et al., 2007; Przeslawski et al., 2008). Loss of reef framework will impact directly on those organisms which either feed or live on live coral, change fish communities (Cinner et al., 2009) which will have serious economic consequences for many people. Tourism revenues will decline and low lying areas which are currently protected from storms will lose this protection and low lying areas will become inundated as sea levels rise. Many of the coastal settlements lack the financial resources to protect these areas and we are already seeing that people are being relocated from such areas.

### Conclusions

While over the past 20 years or so, our understanding of the processes of bioerosion has increased considerably, many gaps remain, especially as to the mechanisms of boring and the interactions between borers and grazers. Our knowledge is best for the Caribbean, Great Barrier Reef, and French Polynesia, with little information available from the Western Indian Ocean, Red Sea, and SE Asia. There is an urgent need to continue studies on the impact which water quality and sediment loads have on rates and agents of bioerosion and how these will change with increasing ocean acidification and rises in seawater temperatures.

As reefs are increasingly being subjected to anthropogenic impacts many of which act synergistically, it is becoming critical to develop monitoring techniques which

could provide an early warning system that a particular reef is under stress and subject to increased rates of bioerosion. In some cases, an increase in densities of echinoids may be sufficient to alert the managers that significant overfishing is occurring, water quality is declining or turbidity is increasing, so that remedial action can take place. An alternative may be to develop methods of quickly assessing the level of sponge colonization of coral rubble as a level of eutrophic conditions. Existing data clearly show that after a massive mortality of corals from a bleaching event, Crown of Thorns plague etc., levels of bioerosion significantly increase and those reefs that do recover are those where water quality is good, turbidity levels are low, and fish populations are healthy, and there are nearby "healthy" reefs that can act as source reefs to re-establish the coral communities. In contrast if these conditions are not met then substantial loss of reef framework occurs and the balance between reef growth and reef destruction is not restored, leading to loss of biodiversity and considerable economic and social consequences of the loss of coral reefs.

## Acknowledgments

The author would like to thank the following for providing references and comments on various drafts of this manuscript, Christine Schönberg, David Bellwood, Winston Ponder, Klaus Rützler, Ian Macintyre and Howard Choat and to David Hopley for the invitation to contribute to this book.

## BIOHERMS AND BIOSTROMES

Jacques L. Laborel  
Université Aix-Marseille, Marseille, France

## Definitions and history

The words were coined by Cumings (1932), a *bioherm* being defined as a *mound or lens-shaped organic build-up, edited by the skeletons of various organisms and lying unconformably inside a stratigraphic series of different lithology*. Conversely, a *biostrome* is a *flat layered reef structure, wide or narrow in shape and causing no stratigraphic disturbance inside its sedimentary environment*. In this original meaning both formations were conceived as *stratigraphic units* and neither the biotic conditions for their development nor steric disposition of their elements were taken into account.

- For the Encyclopaedia Britannica a bioherm is defined as “an ancient organic reef of moundlike form built by a variety of marine invertebrates (and coralline algae). A structure built by similar organisms that is bedded but not moundlike is called a biostrome.”

- For Battistini et al. (1975) a bioherm is a: “lens-shaped organic reef... embedded in situ inside sedimentary layers of different lithological nature... it may be surrounded by a peripheral talus of biodetrital sediments,” whereas a biostrome is a “layered, bank like organic reef of variable extension, creating no discontinuity inside the embedding sedimentary layers.”
- Kershaw (1994) introduces a number of complementary terms: the constructing organisms may be mostly in situ (*autobiostromes*), or mostly as debris included in the structure (*parabiostromes*), with *autoparabiostrome* as intermediate. Conversely, *allobiostromes* are formed of material derived from allochthonous sources, for example skeletal plankton sedimented onto the sea bed.

## Discussion

Although these terms may be useful, there is no general agreement on a complete definition taking into account *at one and the same time* such different characteristics as age, stratigraphic conformity or unconformity, along with the autochthonous or allochthonous nature of deposited organisms. As a consequence, many biologists and geographers use “bioherm” as a general term not only for major biological build-ups such as algal rims or coral reefs (e.g., see Adey and Burke, 1976) but also for small-scale organic build-ups, for which the word “biostrome” would suit better.

Further difficulties come from the fact that relationships with embedding layers are not visible on living formations. For example, an algal rim growing on the outer edge of a coral reef is indeed a bioherm, or a part of it since it takes an active part in the edification and protection of the latter, but a thin algal layer coating a limestone or volcanic shore, or lining a vertical cliff without altering local sedimentation should be called a biostrome even if both formations are in continuity with one another.

Furthermore, actualists consider detrital accumulations of dead shells and broken skeletal material (generally mud-supported and harboring a completely different infauna) as quite different from true build-ups or reefs which are in situ developed formations.

For these reasons bioherm and biostrome cannot be put into automatic correspondence with the highly diversified terms used by actualist reef geologists or biologists, since additional factors such as size of the buildup, thickness, relation with the sea-surface, and resistance to waves must be taken into account. Chronology is also important: most reef complexes are vertical successions of layers corresponding to successive glacial low and high sea-levels.

Initially there was no size limitation in the definition of bioherms and biostromes, and they vary from microbioherms formed by a single colony to coral knolls of decametric size. Nevertheless a general agreement exists to limit the use of the latter words to structures important enough to be easily positioned and mapped.

This, in turn, creates a problem since minor built structures such as algal rims or coral knolls may be of metric or decametric size and difficult to cartography. *In fact, bioherms and biostromes are part of a same continuum.*

Ecological factors are also important.

- *Bioherms*: mainly develop in favorable ecological conditions, growth is three-dimensional, and biodiversity high to oligospecific. Sediment accumulation and diagenesis may be high, leading to *bafflestone*, *framestone*, or *boundstrome* structures (*sensu* Bathurst 1971). Bioherms growing near the surface may lead to true wave-resistant reefs but deep-water coral formations may be called bioherms but certainly not reefs. In the same manner the thick calcareous algal build-ups developing below –30 m (“coralligene”) in the Mediterranean might be called bioherms since, although relatively thin (a few meters thick), they alter both bottom profile and sedimentation (Laborel 1961)
- *Biostromes*: often develop in adverse ecological conditions and their importance depends on such factors as depth, exposure and hydrodynamics, temperature, and sedimentation. They tend to be oligo or monospecific. Algal rims and ridges are linked to strong exposure to surf, as well as pavements of calcareous algae covering the bottoms of reef passes with strong tidal currents. Corals may also develop biostrome-like, for example sheet-like patches of *Siderastrea* along West African and Cape Verde Islands rocky coasts (Laborel, 1974), or western tropical Atlantic *Montastrea cavernosa* developing monospecific layers down to –60 m.

For the geologist, biostromes and bioherms are *fossil* formations - meaning that after their living phase they were killed, eroded, or reworked and covered by younger sediments. Their detail morphology is therefore altered - erosion and sedimentation tending to erode reliefs and fill lower points. This has an over-simplifying effect when using fossil coral-reefs as sea-level markers. Blanchon and Blakeway (2003) recently called attention to such difficulties.

## Conclusions

Unless bio-accumulated detrital mounds and layers are taken out of the definition of bioherms and biostromes and given a different name (a decision that only geologists can take), and the status of small-scale build-ups is settled, *use of the words bioherm and biostrome should preferably be restricted to the fossil formations for which they were coined* (whether their associated detrital facies, and other types of detrital formations are included or not). Students of living reefs are hence encouraged to prefer more general terms (such as “biological build-up,” “reef-like structure,” or “biogenic construction”) instead.

## BIOTURBATION

---

Raphael A. J. Wust  
 James Cook University, Townsville, QLD, Australia

### Definition and introduction

Bioturbation refers to particle mixing within unconsolidated sediments through the activities of biological organisms, most commonly at, or close to, the water-sediment interface. The implications of this process go far beyond simply mixing the substrate as sediment particle preservation, food availability, and geochemical composition within the substrate are all affected. Bioturbation activity can also increase the size of the effective sediment-water interface contributing to enhanced chemical fluxes between the sediment and the water column. Some organisms enhance chemical exchange by flushing their burrows with the overlying waters, a process termed bioirrigation (Aller, 1977). Others, mainly macroinfauna (e.g., annelid worms – polychaetes), feed at depth and eject particles at the sediment-water interface (“conveyor-belt feeders”; Rhoads, 1974). The effective or total bioturbation in reefal environments largely depends on the kinds of organisms present as feeding mode, frequency, and behavior dictate the type of the sediment

mixing. The process of bioturbation is regarded as part of early diagenesis as it contributes to altered physical and chemical sediment nature and structure (e.g., Soetaert et al., 1996). Hence, bioturbation affects sediment biogeochemistry, including organic matter mineralization, oxygen, nutrient, and sulfur cycling as well as oxic and anoxic mineralization (e.g., shell dissolution, Fe and Mn reduction). Therefore, the following discourse discusses some of the most important aspects of bioturbation in reefal environments including the effects of bioturbation on (1) sediment sorting, (2) depth of mixing, (3) time-averaging and preservation potential (i.e., shell age, shell loss, including corrosion and dissolution), and (4) geochemical composition and the oxygen/redox potential within the uppermost sediment layer.

### Effects of bioturbation on sediment sorting and texture

Sediment composition in most reefal environments is dominated by carbonate material originating from local sources. Hence, grain or particle size distributions are poor indicators of hydrodynamic regimes but rather represent the skeleton-producing plants and animals present. Although hydrodynamic sediment sorting takes place in shallow water and within wave-influenced water depths, affecting grains of various buoyancies (e.g., porous *Halimeda* flakes, sea urchin shells or solid molluscs shells), bioturbation appears to have a much more profound impact on sediment sorting and texture. In fact, on the Great Barrier Reef, Australia, several studies have shown that surface sediments in reef lagoons show only short-term sediment sorting due to tropical cyclone activity. Surface sediments became slightly “coarser” following cyclones but reverted to their pre-storm appearance within a few weeks as a result of bioturbation activity (Carter et al., 2009; Gagan et al., 1988; Riddle, 1988).

In reefal environments, typical bioturbators include crustaceans, annelid worms (polychaetes, oligochaetes, etc.), gastropods, bivalves, holothurians, fish, and many other infaunal and epifaunal organisms, which burrow, feed, and rework particles in the uppermost sediment layers. While some of these mainly ingest loose sediments (e.g., worms, holothurians, and fish), they may be responsible for significant sediment mixing as surface sediment turnover rates have been estimated to be as high as 650 kg/m<sup>2</sup>/year (Scoffin, 1992). Although it is difficult to determine absolute sediment turnover and bioturbation rates, the process of bioturbation can lead to significant sediment mixing and sorting. For example, conveyor belt deposit-feeding organisms prevalent in both marine and freshwater systems ingest sediments over a range of depths while depositing gut contents above the sediment surface. This action results in particle-selective transfer of buried materials to the sediment surface and imposes an accelerated rate of sediment and pore water burial within the feeding zone (Robbins, 1986). In the Gulf of California, this sediment sorting activity and the creation

of biogenic stratification by polychaetes forms a distinctive type of biologically produced bedding with fine-grained material 20–40 cm thick overlying coarser material (Meldahl, 1987). Other organisms can also create graded bedding through preferentially moving sediment grains of a particular size, shape, density, or composition.

One of the best-documented bioturbators is callianassid shrimp. These burrowing organisms construct and maintain burrows with species-specific architectures. They ingest sediment material, preferentially, burying gravel-sized grains effectively, sorting sedimentary deposits based on grain size (Bradshaw and Scoffin, 2001; Branch and Pringle, 1987; Meldahl, 1987; Tudhope and Scoffin, 1984; Ziebis et al., 1996). In the Great Barrier Reef region, sediments finer than 1–2 mm are selectively ejected from callianassid burrows and maintained in the surface layer, whilst sediments coarser than 1–2 mm are generally transported to depths between 20 and 60 cm (Tudhope and Scoffin, 1984). Studies from Davies Reef (Tudhope and Scoffin, 1984) and Rib Reef (Kosnik et al., 2009) showed that the top 20 cm contain <10 wt-% particles >4 mm, whilst sediments at 40 cm depth have ~35–40 wt-% particles >4 mm. Hence, the surface sediments are often well sorted, fine grained carbonate debris overlying coarse-grained, poorly sorted, gravely carbonate material. In South Africa, a field study of *Callianassa kraussi* using stained sediments showed that sediment turnover rates were ~60% down to 30 cm depth within 30 days (Branch and Pringle, 1987) demonstrating their effectiveness and high bioturbation rates in reefal sediments. This sediment sorting process means that sediment samples collected from the top ~30 cm on reef platforms are generally poorly representative of the underlying sediments and are not reflective of the accumulating sediments likely to become the fossil record.

Besides sorting sediment, many organisms (e.g., fish, holothurians) also fragment skeletons during feeding. The particle fragmentation and the sediment sorting by burrowing activities lead to selective preservation of the large infaunal skeletons and continuous attrition of the finer (commonly originally framework-derived) sediment. This has been observed by several studies (Bradshaw and Scoffin, 2001; Perry, 1998) such as the work from Davies Reef (Great Barrier Reef, Australia), where pristine bivalves and corroded coral fragments were found side by side at depth (Tudhope and Scoffin, 1984). Sediment turnover by burrowers also inhibits the colonization of the sediments by other infauna or by sessile epifauna and epiflora, whereas seagrass and other rooted vegetation inhibits bioturbation.

### Depth and rate of bioturbation

Depth and rate of bioturbation (i.e., how fast sediments turnover) depends on several factors including environment (lagoon, fore reef, etc.), sediment composition and fauna and flora present. Loosely packed uppermost sediment layers favor effective bioturbation as they provide

food and shelter and yet still may present an oxygenated environment. Although several studies have focused on quantifying bioturbation rates in marine environments (e.g., Grant, 1983; Pillay et al., 2007; Shinn, 1968; Ziebis et al., 1996), little is known about bioturbation rates and depths across various reefal environments. Most bioturbators primarily affect the uppermost 40 cm of the sediment but callianassid burrows often reach depths greater than 2–3 m (Tudhope and Scoffin, 1984; Ziebis et al., 1996). A study from the tropical US Virgin Islands documented the quantity of sediment material being funneled into the subsurface galleries and ejected by *Callianassa* to be up to 2.59 kg/m<sup>2</sup>/day (Suchanek, 1983), whilst a South African field study using stained sediments in callianassid habitats suggested that the turnover rate of sediment material is in the order of 12.14 kg/m<sup>2</sup>/day. Of this material, all of the fragments >1.4 mm remained in the subsurface. In fact, these large turnover rates pertain mainly to the uppermost 20 or 40 cm as these sediments contain the organic material that these bioturbators consume. Therefore, the uppermost 20–40 cm is almost exclusively reworked (Scoffin, 1992). On John Brewer Reef in the central Great Barrier Reef region, analysis of <sup>210</sup>Pb associated with finer sediment fractions showed an actively mixed layer down to ~50 cm (with activity peaking at 19–22.5 cm) and a less actively mixed region from 50 cm to just over a meter (Walbran, 1996).

### Time-averaging and preservation potential in reefal environments

In carbonate environments, bioturbation and the size-selective sediment mixing profoundly influence the geochronological framework and thus bias the age structure of sedimentary deposits. The geochronological framework of carbonate sedimentary sequences in reefal environments is often determined based on relatively few samples, usually one biological specimen per characteristic layer and sometimes the species vary between the selected layers. However, the size-selective process of bioturbation, in particular rapid shell burial, may significantly skew shell preservation (i.e., sediment age structure) as microboring algae, fungi and other organisms, as well as chemical dissolution are most effectively at or very close to the water-sediment interface. This is why many taphonomic studies in the last few decades have focused on a better understanding of the issue of time-averaging as the age structure of modern sedimentary deposits are critical to understand for any study of past and modern sedimentary systems, processes, ecological evolution, etc. (Carroll et al., 2003; Flessa et al., 1993; Kidwell, 2001; Kosnik et al., 2009; Kosnik et al., 2008; Kowalewski, 1996; Meldahl et al., 1997; Staff et al., 1986).

Time-averaging is the range of ages represented in a sample and determines the length of time represented by a stratigraphic unit, and it determines the temporal resolution of a given sedimentary record (Flessa et al., 1993;

Kowalewski, 1996). Time-averaging is fundamentally determined by three largely independent parameters: (1) the rate of sediment accumulation; (2) the characteristics of sediment mixing; and (3) the durability of the individual biological constituents being averaged (Kosnik et al., 2009; Tomasovych and Zuschin, 2009). The sedimentation rate determines the minimum possible degree of time-averaging and in general, higher rates of sedimentation lead to less time-averaging. Rate and depth of mixing determines often the maximum possible time-averaging and deeper and faster sediment mixing leads to more time-averaging (e.g., callianassid shrimps, which effectively sort sedimentary grains by size, shape and/or other characteristics) (Branch and Pringle, 1987; Tudhope and Scoffin, 1984). Durability determines the length of time that a sedimentary grain or fragment remains intact and recognizable. Fragile sedimentary grains/fragments are more likely to be destroyed (i.e., eroded, or dissolved) during mixing leading to less time-averaging, whereas durable grains can be thoroughly mixed without breaking leading to more time-averaging (Kosnik et al., 2009). Taxa with different taphonomic characteristics are, therefore, likely to withstand different intensities of mixing before breaking, and therefore record different amounts of time-averaging even within the same sedimentary deposit. The potential for differential time-averaging has important implications not only for the age model of the deposits but also for the creation of death assemblages and the formation of the fossil record (Cummins et al., 1986; Perry, 1998; Tomasovych and Zuschin, 2009).

It is well known that pre- and post-burial concentrations of skeletal remains pose problems for assessing population densities of individual species, in particular, the recognition of sharp changes in abundance (including plague outbreaks). For example, studies of the abundance of the skeletal elements of the crown-of-thorns starfish *Acanthaster planci* in Great Barrier Reef sediments (Moran, 1992; Walbran et al., 1989a) showed that bioturbation of the sediment is too great to recognize individual historical outbreaks. A similar study following the mass mortality of the Caribbean reef urchin *Diadema antillarum* in 1983 showed that the fossil record of Antillean *Diadema* offers no clues as to whether die-offs had occurred in the ancient past (Greenstein, 1993). Despite the fact that for several weeks immediately after the 1983 mass mortality Caribbean reefs were littered with the long black spines and disarticulated calices of this echinoid, less than a year after the event, the sedimentary record contained no evidence of a marked increase in the remains of *Diadema* (Greenstein, 1991). This may have been the product of the limited sampling method applied or more likely, the extent of physical and biological reworking and chemical breakdown of *Diadema* skeletal elements. In a theoretical approach, it has been suggested that the assessment of the abundance of a species in the fossil assemblage is impossible to determine until the indices are scaled with the indices of other faunal constituents (Pandolfi, 1992). Indices should also be calculated at

several different size classes to provide information on depositional and taphonomic processes.

Species, size, and composition-dependent preservation and mixing potential and its subsequent implication for carbonate sediment composition in reefal environments has received new attention with the advent of amino-acid racemization dating techniques, that, when combined with radiocarbon methods, enable large numbers of specimens to be dated (e.g., Carroll et al., 2003; Kidwell et al., 2005; Kosnik et al., 2007; Kosnik et al., 2009; Kosnik and Kaufman, 2008; Kosnik et al., 2008). The study from the mixed carbonate-siliciclastic shelf of Brazil looking at calcitic brachiopod shells (*Bouchardia rosea*) from four different locations showed that the dated shells vary in age from modern to 3,000 years, with a standard deviation of 690 years (Carroll et al., 2003). The data from four localities displayed significant differences in the range of time-averaging and the structure of the age distribution (i.e., scale and mixing of the sediment columns), implying that environmental factors and local fluctuations in populations of shell-producing organisms are the principal determinants of time-averaging in marine benthic shelly assemblages.

The study of the Rib Reef (Great Barrier Reef, Australia) lagoonal sediments documented significant half-life differences between large and small *Tellina* bivalve shells (Kosnik et al., 2007). There, the top 20 cm of sediment contained almost exclusively living bivalves whilst the sediments in the subsequent 100 cm depth were homogeneously mixed. The youngest shell age at 120 cm depth was 33 years whilst at 30–35 cm depth, the oldest shell was very old (~4,680 years). In addition, comparisons of age distributions and shell half-lives of four molluscan taxa (*Ethalia*, *Natica*, *Tellina*, and *Turbo*) from Rib Reef supported these findings (Kosnik et al., 2009). There, the 428 dated shells displayed the same homogeneous shell stratigraphy below 20 cm depth. Shell half-lives did not coincide with any single morphological characteristic thought to infer greater durability, but correlated to a combined durability score based on shell density, thickness, and shape. The half-lives of the four taxa ranged between ~575 years (*Tellina*) and 1,230 years (*Turbo* opercula). Interestingly, whilst the Rib Reef studies showed a distinct top layer and a deeper age-homogeneous layer, other studies using radiocarbon ages of the bulk carbonate sediments have found stratigraphic consistency, for example, on neighboring John Brewer Reef (Walbran et al., 1989b), but investigations using  $^{210}\text{Pb}$  (associated with finer sediment fractions) also showed that the top 50 cm were actively mixed, whilst the next 50 cm were less mixed (Walbran, 1996).

The study from Caribbean reefal environments in Panama (Kidwell et al., 2005) compared time-averaging and bivalve shell loss in both carbonate and siliciclastic environments and showed that siliciclastic sands and muds contain significantly older shells (median, 375 year, up to ~5,400 years) than nearby carbonate seafloors (median 72 year, up to ~2,900 year). This led to the conclusion that

shell loss rates in carbonate environments are greater as a result of bioerosion and dissolution, which implies greater compositional bias in the surviving skeletal material and leads to the taphonomic trade-off that shells in carbonate sediments show less time-averaging but greater taxonomic bias. Similarly, other studies from Panamanian and the Belize Barrier Reefs also demonstrated the high level of shell damage and dissolution compared to shells in other environments (Best, 2008; Hauser et al., 2009).

The results of these time-averaging studies demonstrate that bioturbation-related selective shell burial favors shells that remain buried through their early taphonomic history. Although buried shells may be brought back up to the surface intermittently by bioturbation or physical reworking (e.g., storms, currents), this exposure is often only for short periods of time. This taphonomic model explains the striking similarities in time-averaging among different types of organisms and the lack of correlation between time-since-death and shell taphonomy. Hence, age estimates in these depositional settings are sensitive to taxon choice and quantify a taxon-dependent bias in shell longevity and death assemblage formation. Most importantly, these conclusions of stratigraphic disorder are not restricted to modern carbonate reefal sediments as studies from other environmental settings, such as tidal flats, etc. have demonstrated (e.g., Best, 2008; Flessa et al., 1993; Tomasovych and Zuschin, 2009). In summary, greater understanding of biases imposed by bioturbation on preservation will ultimately be key to understanding apparent contradictions in modern and past sedimentary records (see also O'Leary et al., 2009).

### Geochemical aspects of bioturbation

Vertical transport and surface sediment mixing mechanisms also profoundly influence biogeochemical processes, microbial communities and hence early diagenesis (e.g., Alongi, 1989; Berner, 1980; Pischedda et al., 2008). In carbonate environments, dissolution of carbonate grains is highest in extensively bioturbated areas (e.g., Aller, 1982; Callender et al., 2002) or very close to the sediment-water interface (Tudhope and Risk, 1985) where oxygen is abundant. Chemical dissolution of particles is accelerated by microboring algae and fungi, which are abundant in coral reef environments. A dissolution study from Davies Reef (Great Barrier Reef, Australia) showed that molluscan shells lost 3% weight over 1 year. Such rates equate to 350 g of dissolved  $\text{CaCO}_3/\text{m}^2$  lagoonal floor/year and represent 18–30% of the sediment influx rate during the Holocene (Tudhope and Risk, 1985).

Bioturbation and bioirrigation (e.g., the exchange of water masses) largely controls the penetration depth of oxygen and organic material into the surface sediments, whilst the consumption of oxygen is influenced by respiration of the benthic organisms as they oxidize organic carbon. In contrast, anaerobic oxidation is almost exclusively mediated by bacterial activity (Berner, 1980). In

reef sediments of Davies Reef (GBR, Australia), sulfate reduction accounted only for 5% of the total organic matter degradation within the top 12 cm with reduction rates averaged  $0.622 \text{ mmol sulfate m}^2/\text{day}$  (Nedwell and Blackburn, 1987). The importance of the biogenic dwellings and structures in carbonate sediment environment lies in the creation of three-dimensional mosaics of oxic/anoxic interfaces in the sediments thus multiplying by several times the volume of the oxygenated sediment (e.g., Kristensen, 2000). Several field and laboratory studies showed that sediment reworking and burrowing activities extended the depth of the oxidized zone (see, for example, Krantzberg (1985) for summary) and are able to create oxidized microenvironments below the aerobic zones (e.g., Myers, 1977; Ziebis et al., 1996). The various bioturbation organisms in reefal environments have distinct bioturbation behavior patterns, which create oxygen distribution heterogeneity. It has been shown that the gallery-builders produced greater spatial heterogeneity due to their complex ventilated structures compared to the burrower species (Pischedda et al., 2008). Moreover, oxygen distribution heterogeneity affects the diffusive oxygen flux as organisms enhance the oxygen exchanges between water and sediments (Ziebis et al., 1996). This outweighs the reduced oxygen flux due to the physical presence of organisms in the biogenic structures or the deposition of mucus along the borrow walls by worms, etc., which may act as a barrier to solute diffusion (Hannides et al., 2005). Furthermore, the process of bioturbation and bioirrigation also actively influences other conditions, such as pH, nutrient status, ammonia, phosphorous, nitrate, and metals contents (see Krantzberg (1985) for summary). Alteration of the diffusive oxygen flux through bioturbation processes by dwelling benthos, such as conveyor-belt feeders or the callinassid shrimps (Ziebis et al., 1996), may also dramatically influence mineralization processes in sediments. Additionally, bioturbation affects biogeochemistry including organic matter mineralization, nutrient and sulfur cycling as shown by a study from the Philippines of alpheid shrimps *Alpheus macellarius* (Holmer and Heilskov, 2008). There, high sediment turnover rates by the shrimps stimulated the mineralization rate.

### Summary and conclusion

Bioturbation refers to particle mixing within unconsolidated sediments through the activities of biological organisms most commonly at or close to the water-sediment interface. In reefal ecosystems, the implications of this process go far beyond simply mixing the substrate as sediment particle preservation, food availability, and geochemical composition within the substrate are all affected, including increasing the effective sediment-water interface that enhanced chemical fluxes (i.e., oxygen, nutrients, sulfur cycling, oxic and anoxic mineralization) between the sediment and the water column. The effective or total bioturbation, part of early diagenesis processes, largely

depends on the kinds of organisms present as feeding mode, frequency and behavior dictates the type of the sediment mixing. The process of bioturbation, therefore, critically impacts reef ecosystems as it influences (1) sediment sorting, (2) depth of mixing, (3) time-averaging and preservation potential (i.e., shell age, shell loss, including corrosion and dissolution), and (4) geochemical composition and the oxygen/redox potential within the uppermost sediment layer.

## BLOWHOLES

Colin D. Woodroffe  
 University of Wollongong, Wollongong, NSW, Australia

### Definition

A blowhole is a crack or fissure in coastal rock through which air and spray is expelled when waves break on the shore.

Blowholes are a feature where large swell impacts coasts, on which the rock contains fractures. Weaknesses, such as joints or fault lines, are preferentially widened, primarily through wave action but also through other processes such as solution of reef limestone. In many cases this can result in a sea cave. Coasts that experience strong swell are impacted by trains of regular period waves generated by remote storms and which have travelled across the ocean. Successive waves trap air into the fissure or sea cave and compress it as the crest of the wave fills the cavity. This pneumatic pressure is released in a spectacular fashion with a deep hiss and an upward spray or blast of water through the cracks [Figure 1](#).

**Blowholes, Figure 1** Several adjacent blowholes on the southern shore of Tongatapu, Kingdom of Tonga.

Blowholes can occur on coasts that are composed of a range of lithologies, and there are a number of swell-dominated coasts on which these regular spouts of spray are a tourist attraction. Lava tubes and dykes can give rise to suitable fissures on volcanic coasts, such as the Taga or Alofaaga Blowholes on Savai'i in Samoa, or Halano Blowhole on Oahu and a blowhole at Nakalele Point on Maui in the Hawaiian Islands. Blowholes are also associated with Tertiary limestones on reef coasts. Where the coast is not protected by a modern reef, spectacular blowholes occur, for example, on the southern shore of Tongatapu, the principal island in the Kingdom of Tonga, and at the eastern end of Grand Cayman, the largest island in the Cayman Islands.

## BLUE HOLE

Eberhard Gischler  
Institut für Geowissenschaften, Frankfurt am Main,  
Germany

Blue holes are underwater karst caves, which when found in shallow water, have striking features because of the strong color contrast between the dark blue cave opening and the light blue surrounding seafloor. A classic modern example is the blue hole in the lagoon of the Lighthouse Reef Atoll in Belize (Figure 1). This blue hole is cylindrical in shape, has a diameter of 300 m and is 120 m deep. It was formed by subaerial dissolution of Pleistocene reef limestone during glacial sea-level lowstands and later roof collapse (Dill, 1977). Giant stalactites found in 40 m depth are impressive evidence of the subaerial cave formation.

Because the lower water column of this blue hole is anoxic, fine-grained bottom sediments turned out to be undisturbed and annually layered. They were used as high-resolution Holocene climate archive (Gischler et al., 2008). Other prominent examples include the blue holes of the Pompey reefs in the Great Barrier Reef of Australia (Backshall et al., 1979), the “puit sans fond” of Clipperton Atoll in the eastern Pacific (Sachet, 1962), the black hole of Andros Island, Bahamas (Schwabe and Herbert, 2004), or the blue hole of Dahab at the fringing reef coast of the Gulf of Aqaba in the northern Red Sea. Even though their depths do not exceed 35–40 m, both the Clipperton and the Andros holes have anoxic bottom water bodies, though the bottom sediments have as yet not been investigated. The depths of the Pompey reef blue holes are also not greater than 40 m and the bottom sediments are coarse-grained. The Dahab blue hole is 100 m deep; scientific studies are missing. The Blue Hole terrains of the Houtman Abrolhos reefs, Western Australia, were recently identified to be growth structures rather than karst features (Wyrwoll et al., 2006). Blue holes may also have more irregular shapes as documented by the many modern examples in the Bahamas (Dill, 1977; Gascoyne et al., 1979). Elongated caves are often related to tectonic structures such as faults and joints that acted as conduits of circulating fresh water during subaerial exposure. Fossil examples of these elongated structures are termed neptunian dikes. They were first described by Fischer (1962) from the Triassic of the Calcareous Alps and are meanwhile known from reefs and carbonate platforms in virtually all Phanerozoic systems. Interestingly, there are several examples of both modern and fossil reefal submarine caves and neptunian dikes that host microbial (“stromatolitic”) structures (e.g., Taylor and Palmer, 1994). Their formation may be explained by the

**Blue Hole, Figure 1** Aerial photograph of the Lighthouse Reef Blue Hole, Belize. The hole is 300 m across and surrounded by a patch reef ring that is interrupted at two locations.

special environments met in caves that can be related to water chemistry (e.g., elevated carbonate concentration), anoxia, low light intensity, lack of physical disturbance, or exclusion of grazing metazoa.

## BOAT CHANNEL

---

Roger McLean  
 University of New South Wales, Canberra, ACT, Australia

## Synonyms

Back-reef trough or tide pool; Moat; Shallow lagoon

## Description

There are two types of boat channels. Artificially constructed boat channels are dug, dredged, or blasted through a reef to allow access to land or wharf facilities. Such channels are usually cut normal to the reef edge or at an oblique angle and require continual maintenance. Natural boat channels, and the ones described in classical reef literature, are depressions that run parallel to the shore and are

generally associated with the back reef area of fringing reefs. Darwin (*Darwin, Charles (1809–1882)*) described an example from Mauritius as a flat space with sandy bottom, located between the outer margin of the fringing reef and the island shore, the depression being sufficiently deep to offer “a safe coasting channel for boats.”

To Darwin the reason for a boat channel was clear; a reef on a sloping surface would at first grow up some distance from the shore, and, because coral on the outer edge would grow much more vigorously than those inshore, a “flat space” would form behind. Others have suggested a more dynamic process, where water driven across the fringing reef by waves and currents, flows laterally out through the boat channel maintaining its form. Because the channels fail to drain completely at low tide they are frequently colonized by marine grasses, algae, and sometimes corals.

Not all fringing reefs have boat channels. Those that do have a myriad of length, width, depth, and continuity scales fully described by Guilcher (1988) with examples of incipient forms from the Gulf of Aquaba, intermediate forms from the Seychelles and Sri Lanka, and well developed forms from Madagascar, New Caledonia, and Lord Howe Island.

Narrow boat channels are also known from atolls and table reefs where they separate the island shore from the reef flat, do not drain completely at low tide, and generally have sparse coral cover because of sediment movement. Such channels are also known as *Moats*.

In a recent review of fringing reef growth and morphology Kennedy and Woodroffe (2002) prefer the less archaic and less ambiguous term “shallow lagoon” rather than boat channel for the back reef depression on fringing reefs. And, they provide details of the 2 km wide and 1.5 m deep shallow lagoon on Lord Howe Island.

## BOULDER BEACHES

---

Jonathan Nott  
 James Cook University, Cairns, QLD, Australia

## Synonyms

Coarse clast beaches; Gravel beaches; Storm beaches

**Boulder Beaches, Figure 1** Boulder beach at Iris Point, Orpheus Island, North Queensland. Photo by D. Hopley.

### Definition

Boulder beaches occur along many of the world's coasts. Their presence and formation is a function of sediment availability and wave energy. Both storm waves and tsunami may be responsible for deposition of boulder beaches but differentiating which of the two may have been responsible, principally, at any one location can be difficult (Nott, 2004). It is common for boulder beaches to display sorting both alongshore but more often perpendicular to the shore with coarser clasts closer to the intertidal zone and progressively fining with distance landward (Figure 1). The shape of clasts varies depending upon the nature of the bedrock from which the clasts were derived and also the depositional processes. Joint spacing in the source bedrock will often limit clast size. Lithology along with the history of transportation and reworking will influence the degree of abrasion and eventual clast shape. Clasts that have experienced a high frequency of reworking and mobilization will theoretically be more rounded whereas clasts that have experienced only one transporting event after erosion from their bedrock source could be expected to be more angular. However, in this last instance the degree of angularity will depend upon the nature of that bedrock source i.e., whether it was composed of rounded core stones in a saprolitic profile or was unweathered jointed rock.

The age of boulder beaches can vary. Hopley and Barnes (1985) identified a potential Pleistocene boulder beach on Orpheus Island, Queensland. Hopley (1984) suggested that many of the boulder beaches on islands and the mainland coast adjacent to the Great Barrier

Reef could have developed during the Holocene high-energy window (8–6.5 kyr) when higher energy swells were able to penetrate into the lagoon of the Great Barrier Reef before reefs had reached sea-level. Other boulder beaches in Queensland are younger than this. Nott (2003) dated coral fragments buried within boulder beaches and found that they were deposited or at least reworked substantially over the past few hundred years. Nott (2003) attributed these accumulations to deposition or reworking by tropical cyclone induced marine inundations.

One of the key and important aspects of boulder beaches in tropical regions is that they can form the substrate for coral reef growth. Hopley and Barnes (1985) observed a fringing coral reef growing on an accumulation of well rounded spherical to oblate shaped lithic boulders 30–40 cm in diameter at Iris Point on Orpheus Island, Queensland. Perry and Smithers (2009) also describe corals colonizing a boulder beach at Stingaree Reef, Queensland. Here these authors suggest the corals grow laterally stabilizing the substrate via “meniscus type bridges” and eventually coalesce with other corals growing on other boulder clasts. It is likely that many boulder beaches appear to have been stabilized by coral reef growth during the Holocene transgression.

In summary, boulder beaches record episodes of changed environmental conditions and high intensity events throughout the Holocene. They can vary in age from Pleistocene to recent and their colonization by coral reefs highlights that reefs do not need initially stable substrates upon which to grow.

## BOULDER ZONE/RAMPARTS

Paolo Antonio Pirazzoli  
 Centre National de la Recherche Scientifique, Paris,  
 France

### Definition

Larger than shingle (20–200 mm in diameter), a boulder is a rock detached from the parent body with size ranging from 256 mm to several meters in diameter. Some degree of rounding has characteristically taken place through abrasion during transport (Carr, 1982).

In coral reef areas, a boulder rampart is a narrow ridge of boulders thrown up along part of the edge of the reef flat, especially on the side from which the prevailing winds blow. The rampart, which should not exceed 1 or 2 m in height, may however reach as much as several meters in some cases (Figure 1). It occurs close behind the lithothamnion (now referred to as *Porolithothamnion*) ridge where it is present (Howell, 1957). In older ramparts that became lithified (Figure 2), the size of boulders, larger than the smaller debris forming a coral conglomerate, is often still recognizable. In areas affected by tropical storms (hurricanes, typhoons, cyclones) the size of the boulders and of the ramparts may increase, and it may be difficult to distinguish them from those left by a major tsunami (e.g., Scheffers, 2005).

Recently, coral-reef bleaching is drastically reducing the coral populations in several areas. Thus skeletal coral

**Boulder Zone/Ramparts, Figure 1** An impressive boulder zone is developed along most of the southern coast of the small (1 km<sup>2</sup>) Tromelin Island (French “Iles Eparses,” Indian Ocean). The outer rampart may reach over 6 m in height and is formed by white boulders left by recent storms. In the upper part of the rampart the boulders are already blackened by Cyanophycean algae, indicating less recent storm deposits. A folded double meter gives scale (15°53′.59 S–54°31′.70 E, May 2009).

**Boulder Zone/Ramparts, Figure 2** Remnant of an ancient boulder rampart, now lithified, reaching 1.9 m above sea level on the north coast of Temoe atoll (French Polynesia). Two coral samples collected at 1.5 and 0.6 m above sea level, have been dated by radiocarbon 3,405 ± 85 year BP (Hv-12667) and 2875 ± 85 year BP (Hv-12668), respectively. At that time sea level was about 0.8 m above present (Pirazzoli, 1987) (photo # 7430, Oct. 1982).

materials are reduced, disrupting the process of forming and maintaining certain boulder ramparts (Williams et al., 1999). The term boulder ramparts, has also been used in glacial areas, indicating deposits left by debris-laden sea ice or by wave-washed remnants of old glacial moraines (e.g., Schwartz, 2005).

## BRAZIL, CORAL REEFS

Zelinda M. A. N. Leão, Ruy K. P. Kikuchi  
Federal University of Bahia, Salvador, Bahia, Brazil

## Synonyms

Coral Reefs of the Southwestern Atlantic

## Definition

Brazil: The largest country in the South American continent, with an area of 8,512,000 km<sup>2</sup> and a coastal zone that extends for approximately 9,200 km.

Brazilian coral reefs: The southernmost reefs of the Western Atlantic Ocean.

## Introduction

French biologist Jacques Laborel (1969, 1970) published the first comprehensive description of the Brazilian reefs. Earlier nineteenth century reports by visiting scientists such as Darwin (1851), Hartt (1868a, b, 1870), and Rathbun (1876, 1878) described the unusual characteristics of the Brazilian reefs: their almost unique mushroom-like growth forms (chapeirão) and the strong endemism and low diversity of the coral fauna. Interest in the studies of Brazilian reefs has increased over the last two decades for several reasons: an increasing number of Brazilian researchers have been studying reefs; reef areas have become increasingly degraded; and Brazilian reefs

have been recognized as an important example of reef growth under marginal environmental conditions. Recent research has included more detailed surveys of the reef environment and the analysis of quantitative databases in numerous articles, theses, and dissertations, as well as technical reports. These publications mainly describe the coral fauna, its endemism, and the adaptation of a low diversity fauna to a highly siliciclastic muddy environment; the fauna and flora of the reef communities; the classification and distribution of the major Brazilian reef systems; the aspects that influenced the Quaternary evolution of these reef systems; and the conservation, protection, and management of these reefs, including reviews of the major natural and anthropogenic impacts that threaten Brazilian coral reef ecosystems.

## Regional setting

The Brazilian coastal zone presents a very diverse suite of environments that evolved during the Quaternary period in response to climate and sea level changes. These evolutionary changes were controlled by variations in the sediment supply and a geological heritage dating to the Gondwana break up in South America and Africa during the Mesozoic period. During the Quaternary period, changes in the relative sea level and climate added younger morphological elements such as tidal flats, wetlands, coastal dune fields, and coral reefs to the coastal zone (Dominguez, 2009).

The continental shelf along the tropical coast of Brazil has a relatively low relief and is very narrow (an average width of 50 km), extending up to 200 km at its southern portion and forming the Royal Charlotte and the Abrolhos banks. The shelf break occurs between depths of 60 and 80 m. Tidal variation range from micro- to meso-tides, with spring tides varying from 1.7 m at the southernmost region to 3.0 m at the extreme north.

According to Bittencourt et al. (2005), the most significant wave front directions are northeast, east, southeast, and south-southeast. North and east waves have periods of 5 s and heights of 1.0 m, while southeast and south-southeast waves have periods of 6.5 s and heights of 1.5 m.

Coral reefs are primarily distributed along the northeastern and eastern Brazilian coast and are less common on the continental shelf in the northern part of the country, a region influenced by muddy sediments from the Amazon River (Figure 1). Nearshore shallow banks and fringing reefs are common within siliciclastic sandy and muddy sediments, and offshore reefs are located in a carbonate-dominated province (Leão et al., 2003).

## Reef-building coral fauna

The Brazilian coral fauna (Scleractinia) has three distinctive characteristics: (a) it has a very low diversity coral fauna (21 species) compared with that of the Caribbean or the Indo-Pacific reefs; (b) the major reef builders are

Brazil, Coral Reefs, Figure 1 Location of major coral reef areas in Brazil.

endemic species from Brazilian waters; and (c) it is predominantly composed of massive corals.

Six of the reef-building Brazilian corals are endemic and some of these species are related to recent Caribbean coral forms while others are related to a Tertiary coral fauna. The archaic species are the most common corals in most modern Brazilian reefs and include the three

species of the genus *Mussismilia*: *M. braziliensis*, *M. hispida*, and *M. hartti*, as well as the species *Favia leptophylla* (Figure 2a–d). The other two endemic species are *Siderastrea stellata* and *Favia grvida* (Figure 2e and f), which are both related to the present Caribbean coral fauna. *M. braziliensis*, *M. hispida*, and *Siderastrea stellata* are found among the massive main frame builders.

**Brazil, Coral Reefs, Figure 2** Endemic Brazilian coral species. (a) *Mussismilia braziliensis*; (b) *Mussismilia hartti*; (c) *Mussismilia hispida*; (d) *Favia leptophylla*; (e) *Favia grvida*; (f) *Siderastrea stellata*; (g) *Millepora braziliensis*; and (h) *Millepora nitida*.

*Mussismilia harttii*, very abundant in most of the reefs, has corallites in dichotomous groups with separated calyces, but does not make branches. *Mussismilia braziliensis* and *Favia leptophylla* show the greatest geographical confinement because they occur only along the eastern Brazilian region. *Mussismilia hispida* has the largest spatial distribution and is found from the northern to the southern regions of Brazil. *Siderastrea stellata* and *Favia gravida* are the most common corals in shallow intertidal pools of the reef tops. The cosmopolitan *Porites astreoides*, *P. branneri*, *Agaricia agaricites*, *A. fragilis*, *Montastrea cavernosa*, and *Madracis decactis* are common in Brazilian reefs. The small *Scolymia wellsii*, *Phyllangia americana*, *Stephanocoenia michelini*, *Astrangia braziliensis*, *A. rathbuni*, and *Meandrina braziliensis* do not contribute substantially to the construction of the reef structure. Recently, three other Caribbean species were described in the Brazilian reefs: *Siderastrea radians*, *S. siderea*, and *Scolymia cubensis* (Neves et al., 2006, 2008). Besides these reef corals, two invasive alien coral species, *Tubastrea coccinea* and *T. tagusensis* were recorded on rocky shores along the coast of the state of Rio de Janeiro (De Paula and Creed, 2004). These exotic corals probably arrived in Brazil on a ship's hull or oil platform in the late 1980s.

Five species of hydrocorals are described on the Brazilian reefs: *Millepora alcicornis*, an important reef-building component in Brazil, predominates on the windward borders of the reefs and is found along the entire tropical coast of Brazil; *Millepora braziliensis* (Figure 2g), found in the high energy zone, is more massive, but has flattened branches in the protected parts of the reefs; *Millepora nitida* (Figure 2h) is currently recorded only along the eastern region of Brazil. Amaral et al. (2008) described a new milleporid species, *Millepora laboreli*, in the northern region of Brazil. Aside from the milleporids, a small hydrocoral, *Stylaster roseus*, is found in the protected parts of reefs in the northeast and east. This species forms small colonies, a few centimeters high, which have a thick base covered with small pointed branches.

### Major reef types

Brazilian reefs comprise two groups of reefs: nearshore and offshore reefs. Nearshore reefs occur on the inner continental shelf and are either adjacent to the coast or are a few kilometers from the shoreline (<5 km). The reefs adjacent to the coast have, at present, part of their reef flats covered by siliciclastic sand. These reefs include fringing reefs and shallow bank reefs. The fringing reefs usually border the shore of the islands up to several kilometers, developing above the island substrate as a continuous fringe. This fringe became narrower with the lowering of the sea level that occurred in the late Holocene and, thus, shortened the reef distance from the shoreline and partially buried the back-reef lagoon. The fore-reef depths can vary from 5 to 10 m. A very shallow lagoon (1–2 m deep) is common in the back-reef area where small patch reefs

and coral knolls are observed. Meandering channels may occasionally interrupt the reef crest. The attached banks also occur adjacent to the beach but are of limited lateral (alongshore) extent. Generally these bank-type reefs do not exceed more than 1 km in length. The entire reef flat is located in the intertidal zone and no lagoon is formed. Tidal pools are common, generally of a reduced extent, say 5–10 m in width and usually not exceeding 1 m in depth. The reef front depth varies from 5 to 10 m and reef walls are generally abrupt.

Offshore reefs consist of reef structures of variable dimensions, from a few meters to 20 km, and are located more than 5 km off the coastline in various water depths. These reefs do not form a lagoon, and sediment transport occurs freely on the leeward side of these reefs. The offshore reefs include the following types of reef: coral knolls, patch and bank reefs, and coral pinnacles. Coral knolls can attain maximum dimensions and heights of a few meters, and are usually found at depths of less than 5 m. Patch reefs have lateral dimensions of tens of meters with the widths and lengths of the reefs being larger than the heights. The lateral walls may have a high relief of approximately 5 m. They are sparsely distributed over wide areas of the Brazilian inner shelf. The isolated bank reefs are reef structures which have horizontal dimensions ranging from approximately 50 m to tens of kilometers, and their heights above the sea floor vary from 10 m (shallow banks) to more than 20 m (deep banks). This reef type has variable shapes (irregular, circular, elongate, arc-like, etc.) and is controlled by its substrate or by its position relative to the present day sea level. Elongate reefs developed on the lines of beachrock - features that are widely distributed along the northeastern and eastern regions of Brazil. Larger and irregular bank reefs, such as those of the Abrolhos area which established on the topographic highs left by the erosion of older reef carbonates, are also included in this category. Most are flat-topped reefs that were truncated during low sea level stands, thereby favoring lateral rather than vertical growth. Submerged banks, a few meters high, are found in depths up to 20 m, and may be related to erosional phenomena followed by relative sea level oscillations. Distinctive isolated coral pinnacles range in height from 5 to 25 m above the sea floor, while the diameter of their tops ranges from 5 to 50 m. These reefs can be of two types: (a) columnar, where the base is equally as wide as or wider than the top of the reef; and (b) chapeirão, where the flat top is wider, sometimes over three times larger than its base. Chapeirão is a term introduced by Charles F. Hartt in 1870, which alludes to hats with broad brims. This coral growth form is unique to Brazilian reefs and consists of isolated narrow pillars whose tops are expanded laterally, resembling flat mushrooms (Hartt, 1870). Seen from above, these structures have an almost perfectly rounded shape and are easily mapped from aerial photographs. Aside from these reefs, two other types of oceanic reefs are found in Brazil: (a) shelf edge reefs that grow at the border of the continental shelf, with widths up to 3 km and a relief of 35 m at depths

of 50 m (Kikuchi and Leão, 1998). These reefs must have been initiated earlier in the Holocene at lower sea levels, and are now veneered with a deeper water community; and one atoll reef, Rocas, that has dimensions of 3.5 km by 2.5 km. Despite its small dimensions, a reef front, reef flat, and lagoon can be clearly distinguished and subdivided into discrete features. This reef mostly comprises nonarticulate coralline algal growth (Kikuchi and Leão, 1997; Gherardi and Bosence, 1999).

## Summary

Brazil has the most extensive and rich coral reefs in the Southwestern Atlantic Ocean. The reefs are characterized by their unusual growth forms, which have mushroom-shaped pinnacles that can fuse together on their tops, forming larger reefs structures that include the following: (a) shallow small isolated reefs that occur adjacent to the shoreline and often have elongated forms; (b) bank reefs off the coast that have widely variable sizes (<10 to >20 km) and shapes; (c) shallow fringing reefs which mostly border the coasts of islands; (d) open sea coral pinnacles, named “chapeirões”, which usually occur in depths greater than 20 m; and (e) drowned reefs at the middle and outer continental shelves. The coral fauna of the Brazilian reefs has a very low diversity (21 species) and a high degree of endemism. The major reef builders are relic forms, remnant of an ancient coral fauna dating back to the Tertiary, and lack completely branching growth forms. Brazilian reefs initiated growth after 8 ka BP, a notable period of coral expansion in the tropical world, but an incipient forced regression related to a sea level decrease of approximately 2–5 m during the last 6.0–5.0 ka had a significant influence on the evolution of the reef structures.

## Synonyms

Ectoprocta; Ectoprocts

## Definitions

Bryozoa: A phylum or superphylum of aquatic (mostly marine) invertebrate animals, tiny (half-mm-sized) polyp-like individuals (*zooids*) with U-shaped digestive

tracts and occupying hardened (usually calcareous) exoskeletal chambers (*zoecia*), joined together in small to moderate-sized (cm-sized) colonies (*zoaria*). The vast majority are eucoelomate, comprising the subphylum or phylum *Ectoprocta*, so that at times the two Latin names have been used interchangeably.

Reefal bryozoans: Reef-dwelling bryozoans; bryozoans found on or within coral-reef frameworks, rubble, and flanking sediments.

### Introduction: Bryozoans in modern reefs

Bryozoans are found worldwide, from tropical to polar, and shoreline out to deep ocean. Some occur on reefs in warm shallow seas. Those colonies (Figure 1) are most often thin crusts whose upper surfaces exhibit many tiny pin-prick-like holes; other zoaria are thicker crusts or masses, flexible tufts, low-standing branches or lattices, and encrusting networks (Cuffey, 1973).

On closer examination, most of the reefal colonies can be seen to consist of short box-like zooecia and therefore belong to the order *Cheilostomida*, by far the most abundant and diversified of the living bryozoan groups (Cuffey and Utgaard, 1999, p. 208, 210). The others are made of long tube-like zooecia, representing the order *Cyclostomida* (Cuffey and Utgaard, 1999, p. 208–209, 211).

### History of discovery

In the early days of scientific study of modern coral reefs, bryozoans were overlooked by reef workers, due to their small crust-like colonies being inconspicuous compared to the larger coral heads and branches dominating reef surfaces.

In those days, taxonomic or faunal studies of bryozoans of large regions including reefs would contain scattered notes on certain species that had been found on coral or rock here and there, but not as any systematic analysis of reef-related occurrences. Examples include Egypt (Audouin, 1826), Tanzania (Ortmann, 1892), *Florida Keys* and the (Smitt, 1872–1873; Canu and Bassler, 1928; Osburn, 1940), and the Philippines (Canu and Bassler, 1929). Many such records were drawn together by Winston (1986).

Beginning about 1970, field studies specifically targeting bryozoans in living reefs revealed substantial numbers of bryozoans, particularly on the *Bermuda* and *Enewetak Atoll, Marshall Islands* (Cuffey, 1970, p. 44–45, 1972, 1973). Since then, a number of modern reefs examined for bryozoans have been found to also have significant bryozoan components, as for example the *Great Barrier Reef: Origin, Evolution, and Modern Development* (Ross, 1974; Ryland, 1974; Cuffey, 1978) among Pacific Coral Reefs (*Pacific Coral Reefs: An Introduction*), the Virgin Islands (Schopf, 1974), *Bahamas* (Cuffey and Fonda, 1977), and *Jamaica* (Jackson and Buss, 1975; Jackson and Winston, 1982) among Atlantic and Caribbean reefs.

### Extension into the fossil record

Present-day types of bryozoan involvement in coral reefs go back to at least mid-Cenozoic time (approximately 30 ma). Miocene, Pliocene, and Pleistocene fossil reefs often exhibit bryozoan crusts among the corals in the same manner seen on living reefs, as figured in the Late Pleistocene (125 ka) reefs in the *Florida Keys* (Cuffey, 1977, p. 187–188) and noted in the Early Miocene uplifted atoll of *Makatea* (Cuffey and Montaggioni, 1986) and the Latest Miocene reefs in Algeria (Hamdane and Moissette, 2002).

Further back in geologic time, bryozoans occur in earlier fossil reefs or *Bioherms* and *Biostrome*, but their participation therein can be understood in terms of expansions of their roles (Cuffey, 1977) as initially defined from modern reefal bryozoans (Cuffey, 1972) (*see next section*). The Bryozoa originated long ago (Ordovician Period, early in the Paleozoic Era, roughly 475 ma), evolved into different classes and orders (some now extinct; Cuffey and Utgaard, 1999), several of which participated in reefs at various geologic times.

### Roles seen among reefal bryozoans

The manner in which bryozoans occur on modern reefs has obvious implications about how their calcareous skeletons might contribute to reef building or reef communities, the *constructional or ecologic roles* played by these animals. These roles were initially defined for modern

**Bryozoa, Figure 1** Reefal bryozoan groups, identifiable by their distinctive colony shapes (*zoarial forms*); aeteids and reteporids are also cheilostomes, while crisiids, idmoneids, and lichenoporids are cyclostomes. From Cuffey (1973, p. 30).

**Bryozoa, Figure 2** Roles played by bryozoans in modern coral reefs. After Cuffey (1972, p. 547).

coral reefs (Figure 2; Cuffey, 1972) and later expanded to cover both living and fossil reefs (Cuffey, 1977).

Most of the bryozoans encountered on modern coral reefs are *hidden encrusters* (Cuffey, 1972), their colonies attached to the undersides (Figure 3) of coral branches, fronds, or heads, and of reef-rock fragments, rubble, or ledges, as well as of shells or other hard substrates (both natural and artificial). Equivalent terms used later for this principal reefal-bryozoan role include *coelobites*, *coelobionts*, *cryptobionts*, and *cryptic fauna*; hidden encrusters comprise the bulk of the wider category of *accessory frame encrusters* (Cuffey, 1977). During life, such bryozoan colonies compete for attachment space with other sessile organisms – serpulids, certain pelecypods and gastropods, sponges, encrusting foraminiferans, and various calcareous algae like lithothamnioid *corallines*.

In addition to the sheltered undersides of the coral framework, there are deeper, darker niches, recesses, and cavities within modern reefs. These may also contain bryozoan crusts, ranging from thin and unilaminar to thicker and multi-layered, locally even filling those spaces. Such bryozoans can be described as *cavity dwellers* or even *cavity fillers* (Cuffey, 1972, 1977); their calcareous encrustations can contribute to reinforcing or strengthening the overall reef framework.

Modern reefs include very few actually built by bryozoans themselves. However, three are now known – *Bahamas* (Joulter Cays tidal channel, Cuffey et al., 1977), *Netherlands* (coastal ponds, Bijma and Boekschoten, 1985), and *Australia* (Coorong Lagoon; Bone and Wass, 1990) – all quite small, of limited diversity, and in ecologically marginal habitats compared with flourishing coral reefs.

In contrast, at several phases in the geologic past, different bryozoan taxa constructed reefs or *Bioherms* and *Biostromes* of various sizes (Cuffey, 1977, 1985, 2006).

Bryozoans might be expected to be important sediment formers on and around modern coral reefs, since their colonies are common on many such structures. Surprisingly, however, examination of loose sediments surrounding living reefs reveals only occasional small fragments of broken bryozoans (Cuffey, 1972). Clearly, cheilostome crusts' microstructure proves to be comparatively weak and quickly destroyed when eroded off the reefs. In contrast, some fossil reefs are surrounded by clastic carbonates composed entirely of bryozoan detritus (Pitcher, 1964; Cuffey, 1977).

Bryozoan-rich sands do cover parts of the present-day continental shelves around Australia, including some of the individual reefs within the *Great Barrier Reef: Origin, Evolution, and Modern Development* complex (Maxwell, 1968, p. 190, 205–208). However, their colony forms and presumed species identities do not match those observed on the actual reefs (Cuffey, 1978), so these bryozoans do not appear to be strictly reefal in the sense talked about throughout this article, but probably inhabited deeper bottoms between the individual reefs. This suspicion is reinforced by the discovery of extensive similar bryozoans-rich sands extending south into clearly non-reef regions (Wass et al., 1970).

Various other minor roles have been noted for bryozoans, some in modern reefs, but most in ancient fossil *Bioherms* and *Biostromes* (Cuffey, 1972, 1977, 2006). One species seen in Bermuda, the Bahamas, and Florida, *Membranipora* or *Jellyella tuberculata*, encrusts

**Bryozoa, Figure 3** Typical field appearance of reefal bryozoans (hidden encrusters; pen-points for scales); (a) underside of Bermuda brain coral (*Diploria*) encrusted (center) by cheilostome *Steginoporella magnilabris*; (b) undersides of Bonaire flat cobbles (broken *Millepora* blades), bearing several small round cheilostome crusts (the one closest to pen-point is *Trematoecia turrita*).

*Sargassum* brown algae drifting through surface waters around the reefs and so is often found washed up on nearby beaches. In older fossil reefs, branching and lattice bryozoans inhibited movement of loose sediments around reefs, functioning as *sediment baffles*, *trappers*, *binders*, or *stabilizers*. In other reef structures, dead coral bioherms' surfaces were covered by a solid veneer of encrusting bryozoans. In still others, originally more extensive bryozoan crusts appear so corroded and partially dissolved that they obviously served as a source of dissolvable carbonate during diagenesis.

### Continuing investigations

After elucidation of the reefal bryozoans' roles, investigations of these animals have continued, diversifying into several different types of studies.

Most immediate have been documenting species identities and distributions within various living reefs like *Bermuda* (Cuffey and Fonda, 1986), *Enewetak Atoll, Marshall Islands* (Cuffey and Cox, 1987), *Belize* (Winston, 1984), *Bali* and other *Indonesian Reefs*

(Winston and Heimberg, 1986), the *Solomons* (Tilbrook, 2006), and others.

In addition to these faunal studies, others have focused on particular reefal-bryozoan species' ecology (Cuffey and Foerster, 1975; Cuffey and McKinney, 1982) and interactions like competitive overgrowths (Jackson, 1979). A few new species have been reported from certain remote reefs like *Enewetak Atoll, Marshall Islands* (Cuffey and Cox, 1987); otherwise, known reefal species do not appear to be restricted exclusively to reef habitats. Within-species variability, particularly in colony form, can in certain species be related to wave energy; *Schizoporella errata* in *Bermuda* grows into compact nodular masses under turbulent conditions, but erect open branches in quiet situations (Cuffey and Fonda, 1976).

Modern coral reefs exhibit *Geomorphic Zonation*, the best example of which is the *Atlantic/Caribbean Forereef/Reef Front* corals (shallow *Acropora palmata*, middle *Acropora cervicornis*, and deep *Montastrea annularis*). Reefal bryozoans however, do not show such depth-related species assemblages; instead, the various species' depth ranges overlap progressively and gradually, going down the *reef front (Forereef/Reef Front)*, as documented on Bonaire's reef-slope (Kobluk et al., 1988). The particular individual species' depth ranges may prove useful in paleoecologic interpretations, however, even if multispecies assemblages can not be recognized. Moreover, depending on the number and abundances of the shallowest species, a diver in the field may observe that some reefs have abundant bryozoans from the sea-surface on down, whereas others show common colonies only below 10 m or 30 ft (like *Bermuda* and *Enewetak Atoll, Marshall Islands* respectively; Cuffey, 1973).

In contrast to vertical or depth *Geomorphic Zonation*, reefal bryozoans in some cases show horizontal *Geomorphic Zonation*, related to distance from shore or open ocean. Reefal (i.e., off-shore) versus in-shore species suites can be recognized in *Bermuda* (Fonda and Cuffey, 1976), as can diversified outer-reef versus restricted lagoonal-reef assemblages in the *Bahamas* (Cuffey and Fonda, 1977).

Traditionally, reefal bryozoan species have been identified by examining their colonies' horizontal upper surfaces. However, those surfaces are often covered, not visible, when reef masses are cut into by quarrying, road-cuts, or ship groundings, and hence their bryozoans' appearance in vertical cross-sections must be used instead for identifications to determine the particular species involved in those reefs. Taxonomists have not usually published such views, and thus work has begun on coordinating surface with cross-section appearances (Kosich and Cuffey, 1978). Preliminary results have been used successfully on modern bryozoan reef rock at Joulter's Cays (Cuffey et al., 1977).

A great many other aspects of bryozoan involvement in modern and geologically recent fossil reefs could be analyzed – physiologic, biogeographic, pharmaceutical, geochemical, etc. However, not enough time nor workers

have yet become involved with reefal bryozoans for such greater scientific diversification to have developed so far. Much remains to be done!

## Summary

Although initially overlooked by reef scientists, bryozoans living on or in modern coral reefs are common and diversified on many such structures, particularly in their principal role as hidden encrusters. Much detailed work needs to be done yet to fully elaborate many aspects of reefal bryozoan taxonomy, distribution, and ecology.

## CALCITE

Sue J. McLaren  
University of Leicester, Leicester, UK

### Definition

The minerals calcite, *aragonite*, and *vaterite* are naturally occurring polymorphic forms of calcium carbonate ( $\text{CaCO}_3$ ). At normal Earth surface pressures and temperatures, low magnesian calcites are the only stable  $\text{CaCO}_3$  phase. Calcite has a trigonal crystal system, perfect cleavage in three directions, conchoidal fracture, and a hardness of three on Moh's scale. Calcite often has a massive habit, although dog-tooth spar (scalenohedrons) and rhombohedral forms are also common. The mineral's color is commonly white or colorless, but may be yellow, pink, pale blue, or even red in hand specimen; in thin section, it is colorless. Most calcite is relatively pure, but impurities include ferrous iron, magnesium, manganese, and strontium. Calcites with less than four mole percent  $\text{MgCO}_3$  are termed low magnesian calcites, while those containing 4–30 mole percent are known as high magnesian calcites. Calcite is readily soluble and effervesces vigorously in cold dilute hydrochloric acid and it is stained red by the organic dye Alizarin Red S.

Calcite is generally a major constituent of carbonate rocks and is a commonly found earth mineral. Limestones must be made of more than 50% carbonate minerals (Tucker and Wright, 1990). Calcite tends to precipitate from freshwater where Mg:Ca ratios are generally low (<1). Carbonate minerals are highly soluble in waters rich in carbon dioxide, which results in most limestones being susceptible to *diagenesis*. *Diagenesis* leads to the alteration of a carbonate deposit by various geochemical processes that result in changes in mineralogy, texture, and fabric.

Over time, skeletal and non-skeletal carbonate grains and carbonate matrix alter to low magnesian calcite and calcite cements are precipitated in primary and secondary pore spaces. In the process, *aragonite* is often partially or totally dissolved. During transformation from high to low magnesian calcite, the initial structure is kept but  $\text{Mg}^{2+}$  is leached from the crystal. The crystal sizes of calcite cements that form can be grouped into *micrite* (<4 microns), *microspar* (4–10 microns), and *spar* (>10 microns).

Typical freshwater low magnesian calcite-rich deposits include *calcretes*, tufa, travertine, cave speleothems, and *eolianites*. High magnesian calcites are common components of *beach rocks*, shallow marine sediments, and the skeletons of marine organisms. According to Mackenzie et al. (1983), there is an increase in the content of magnesium within skeletal high magnesian calcite from polar regions towards the tropics, which is related to changes in temperature and seawater saturation of carbonate ions.

## CALCRETE/CALICHE

Barbara H. Lidz

U.S. Geological Survey, St. Petersburg, FL, USA

### Synonyms

Breccias; Calcium-carbonate cement; Hardpan; Impermeable crust of soluble calcium salts; Laminated crust; Pedogenic calcareous soil; Secondarily deposited calcareous material on native-limestone surface; Soilstone crust; Strongly indurated wafer-thin calcareous layers; Subaerial  $\text{CaCO}_3$  crust; Subaerial-exposure surface; Unconformity

### Definition

Laminated subaerial-soilstone crusts (calcrete/caliche) are found in diverse carbonate environments throughout geological history (e.g., Swett, 1974; Harrison and Steinen, 1978; Kahle, 1978). Florida crusts accrete vertically in a series of wafer-thin layers, through capillary interaction of wet/dry processes on exposed limestone (Multer and Hoffmeister, 1968). The limestone underlies a thin mantle of organic-rich soil that contains cryptocrystalline calcite, derived from periodic dissolution of in situ carbonate particles. Drill cores show Florida crusts cap five Pleistocene chronostratigraphic marine sequences, as unconformities (Enos and Perkins, 1977). Extensive subsurface persistence renders the crusts significant stratigraphic markers for regional sequence correlation. Radiometric dates that correlate with Pleistocene glacial cycles indicate times when subsurface crust-source sites were dry land (Robbin, 1981). In the Florida Keys, crust accretion rates are uniform within, but inconsistent between, northeast (1 cm/2 ka) and southwest (1 cm/4 ka) sites (Robbin and Stipp, 1979). Inconsistency results from different local ambient conditions during crust formation (e.g., variability of limestone porosity, soil, humus, detrital carbonate, and erosion). Inconsistent accretion rates result in different thicknesses of calcrete (see Figure 1a and b in entry entitled, *Porosity Variability in Limestone Sequences*).

### Calcrete textures

Calcretes have various textures depending upon the type of material present at the site of formation and/or the processes involved in formation. Rhizoliths or rhizoconcretions are small cylindrical or conical root-cast structures, usually branching or forked, that form in a sedimentary rock. Rhizoliths may consist of calcrete or chert and resemble in shape the plant roots they have replaced. Calcretes that consist of aggregated, clustered, or flocculated grains are said to be clotted. Patches of dark, dense, fine-grained areas ultimately surrounded by sparry calcite can characterize clotted rocks. The squashing of soft micrite pellets usually produces clotting. Calcretes that have different colors, commonly resulting from oxidation of iron components, are said to be mottled, but

**Calcrete/Caliche, Figure 1** (a) Large, angular, naturally blackened pebbles embedded in brown, layered, fine-grained calcrete form a breccia (compare with calcretes shown in a and b in entry entitled, *Porosity Variability in Limestone Sequences*). Sample is from Ramrod Key (lower Florida Keys). Ramrod Key limestones also contain charred twigs (charcoal; not shown). Charcoal in 5-ka calcrete indicates natural forest fires occurred before the invasion of modern man. (b) A multicore breccia was collected at a depth of ~6 m below sea level from quarry tailings in a solution pit on Big Pine Key (lower Florida Keys). The sample was cut, and the left part artificially blackened in the laboratory by heating at 400°C for one-half hour to reproduce darkening similar to colors of blackened pebbles widely found in the Florida-Caribbean Pleistocene and Holocene record. Note layered calcrete crust on left side of specimen. Blackened fragments include preexisting calcrete and fossiliferous Key Largo Limestone (coral). Original rock colors are visible in unheated section at right. Rulers in both photos are 2 cm long. See Figure 2a in entry entitled, *Florida Keys*, for locations of Ramrod Key and Big Pine Key.

multicoloration is not the only characteristic. Mottled calcretes also can contain small irregular pieces of material in a sedimentary matrix of a different texture.

Breccias are coarse-grained clastic rocks composed of angular fragments of any kind of preexisting native rock. Mineral cement binds the fragments together in a fine-grained matrix of sand, clay, or calcrete. Breccias may result from talus accumulation (sedimentary breccia), igneous processes (volcanic and explosive breccias), tectonic processes (fault breccia), disturbance during

sedimentation (intraclastic breccia), or collapse of rock material (solution and collapse breccias). Solution and collapse breccias are common in karst settings such as Florida where sinkholes and other types of karst features form. Also common in Pleistocene and Holocene limestones throughout the Florida-Caribbean region are multihued blackened limestone pebbles in a calcrete matrix (Figure 1a and b). Simple laboratory (heating) experiments and observations (campfire sites) have shown that pebbles of limestone (coral, mollusc, grainstone, and calcrete) can blacken almost instantaneously when heated to between 400° and 500°C (Shinn and Lidz, 1988). Being the lightning capital of the U.S., Florida has, and has had in the geological past, no shortage of sources of ignition for lighting of natural forest fires.

## CARBON FLUXES OF CORAL REEFS

---

Marlin J. Atkinson  
 Hawaii Institute of Marine Biology, Kaneohe, Hawaii

## Synonyms

Carbon dynamics

## Definition

The carbon fluxes of coral reefs are the rates of carbon exchange between sea water and reef organisms, communities, and habitats. They characterize key biochemical processes such as photosynthesis, respiration, and calcification, as well as important biogeochemical transformations such as diagenesis and dissolution. Fluxes are reported as rates of exchange per area.

## Introduction

A coral reef is a living structure that maintains itself at sea level by the combined biogenic calcification of a variety of taxa. A healthy, sustainable coral reef ecosystem is comprised of diverse communities that capture and utilize energy from sunlight, waves, and organic particles. The motivation for studying carbon fluxes of coral reefs is to delineate and characterize these rates of energy transfer in order to compare reefs with other ecosystems and to compare among reefs, and to predict responses of reefs to natural or anthropogenic perturbations.

Specific communities within a coral reef ecosystem achieve high rates of photosynthesis and, consequently, production of organic carbon. Over the past 80 years, a variety of ideas have been advanced to explain these high rates of carbon production. One prevalent view is that close physical and ecological relationships between autotrophs (organisms such as plants that produce organic carbon from inorganic carbon) and heterotrophs (organisms that consume organic carbon, i.e., most animals) create an ecosystem where plant nutrients (compounds of nitrogen, phosphorus, sulfur, etc.) are either retained within the biota or recycled within the community, maximizing carbon production. A more recent view is that coral reefs produce organic carbon that is low in nutrients and is quickly respired. This article provides an overview of the carbon dynamics or carbon fluxes of coral reefs.

## Fluxes of dissolved inorganic carbon

The amount of carbon, in both dissolved and particulate forms, is orders of magnitude lower in the water column above a coral reef than it is in the biota or in the sediments (Table 1). Dissolved inorganic carbon (in the form of dissolved carbon dioxide and carbonate and bi-carbonate ions) is removed from the water column by autotrophs and converted to, or “fixed” into, both organic compounds (tissue and dissolved organic compounds) and inorganic compounds (notably calcium carbonate skeletons of marine algae and corals; Kinsey, 1985; Hatcher, 1997; Gattuso et al., 1998; Atkinson and Falter, 2003). The total amount of carbon fixed into organic matter per day is termed gross primary production. Gross primary production is typically estimated by adding daytime net photosynthesis to the 24-h respiration rate, based on dark respiration. Light respiration can be up to two times greater than dark respiration. Published values of gross primary production that assume light respiration equals dark respiration are therefore of questionable accuracy

(Langdon et al., 2003). In practice, flux of oxygen is used instead of carbon dioxide to estimate net photosynthesis and respiration, assuming photosynthetic and respiratory quotients of 1.0 (range 0.8–1.2). Many such measurements have produced a uniform “metabolic standard” for reefs (Table 2).

Gross primary production varies from 100 to 2,000 mmol C m<sup>-2</sup> d<sup>-1</sup>, depending on habitat (Table 2). Sand communities have the lowest production (100–300 mmol C m<sup>-2</sup> d<sup>-1</sup>), with reef flats being moderate (350–500 mmol C m<sup>-2</sup> d<sup>-1</sup>), and communities with high surface area of coral and algae exhibiting maximal values (1,000–2,000 mmol C m<sup>-2</sup> d<sup>-1</sup>). These metabolic rates are consistent between reefs, suggesting that they are independent of species composition. Thus, carbon metabolism on reefs has a tri-modal distribution (Table 2), and estimates of carbon production and calcification (production of calcium carbonate) can be made based on knowledge of bottom type or habitat. These three basic habitats of

coral reefs can be easily identified and mapped with airborne and satellite imaging systems (Hochberg et al., 2003). Ecosystem-wide estimates of gross primary production are possible by applying average metabolic rates to the areal extent of those habitats (Andrefouet and Payri, 2000). Gross primary production can also be estimated by measuring the number of photons absorbed into the benthos with remote-sensing image data and multiplying by 0.033 mol oxygen/mol photons (Hochberg and Atkinson, 2008). Thus, the amount of energy converted from tropical sunlight to organic matter on a reef flat represents about 3% efficiency. Sunlight incident on tropical reef flats is typically ~30–40 Einstein m<sup>-2</sup> d<sup>-1</sup> or 10,000 kJ m<sup>-2</sup> d<sup>-1</sup>, whereas 1 mol organic C m<sup>-2</sup> is about 400 kJ m<sup>-2</sup>.

Community respiration varies over the same range as gross primary production (Table 2). Benthic communities with high gross primary production tend to exhibit high community respiration, indicating much of the respiration of organic material occurs within the habitat. Most of the respiration probably occurs within the organisms that fix the carbon; some is the result of consumption and/or microbial decomposition of organic detritus. Measurements of production and respiration over periods shorter than 1 week do not adequately reflect longer-term net ecosystem metabolism. This is because in the case of autotrophs, a day's gross primary production depends on cumulative ambient light on that day; the daily gross respiration depends on the amount of stored photosynthate on that day (Falter et al., 2001).

### Net production of carbon

Net community production (NCP – Table 2), the excess carbon produced over a 24-h period (gross primary production minus community respiration), varies among habitats. In classic reef zonation, more carbon is produced than is respired on the fore-reef and algal crest, instead being exported to the back-reef area as detritus and dissolved organic carbon. As it is carried across the reef, a proportion of it is utilized by downstream heterotrophic communities (Crossland et al., 1991; Kinsey, 1985). In practice, the delineation between producer and consumer habitats is not always clear. For example, many back reef

**Carbon Fluxes of Coral Reefs, Table 1** Mass of carbon (C) in mmol m<sup>-2</sup> in 1 m of the water column above the benthos, in the living benthos (autotrophic and heterotrophic), and in the top-most 1-m of sediments (solid and dissolved phases)

| Pool             | C                    |

areas that have significant coral rubble can have high net production. Thus, much of this zonation of production and consumption is dependent on the nature of the substrate. Sand and mud have a tendency to be heterotrophic (negative net production), while areas exposed to high water motion and hard substratum with algae tend to be autotrophic (positive net production). Rich coral areas and knolls usually have high gross production, but a net production that is close to zero. Seaward areas with a relatively high net production can be sustained by dissolved nutrients in the incoming ocean waters, and where high water motion can support higher nutrient uptake and photosynthetic rates than calmer areas (Hearn et al., 2001; Carpenter and Williams, 2007). Nutrient uptake is proportional to nutrient concentration and water velocity, with a coefficient of proportionality that is directly related to the friction of the water flowing over the bottom communities (Atkinson and Falter, 2003). The energy dissipated as bottom friction helps drive net photosynthesis and net production of carbon, and is of order  $1,000 \text{ kJ m}^{-2} \text{ d}^{-1}$  (Hearn et al., 2001), or about 10% of the energy in sunlight for typical cross-reef currents. Organic carbon production has high ratios of carbon:nitrogen:phosphorus (C:N:P), reflecting dominant production by macrophytes (Atkinson and Grigg, 1984).

### Fluxes of planktonic carbon

Coral reef communities take up suspended planktonic organic matter (detritus, phytoplankton, zooplankton) as a source of “new” carbon – i.e., carbon they do not fix themselves via photosynthesis (Ayukai, 1995; Ribes et al., 2003; Yahel et al., 1998). Reported rates of particulate carbon uptake are, however, relatively low ( $<40 \text{ mmol C m}^{-2} \text{ day}^{-1}$ ), compared to rates of gross primary production and community respiration (Table 2). Suspended organic matter is thus relatively unimportant as a source of carbon for many hard and soft coral communities. However, it is an important source of specific essential nutrients for many communities, and food for some (Fabricius et al., 1998; Sebens et al., 1997).

### Fluxes of dissolved organic matter

Dissolved organic carbon comes from microbial decomposition of plant and animal detritus and fecal material. It is ubiquitous in water over coral reefs, and it typically occurs at concentrations much greater than those of particulate organic matter ( $50 \text{ mmol m}^{-3}$ ). Dissolved organic carbon is taken up and released by a variety of organisms, including corals and sponges (Schlichter and Liebezeit, 1991; Hoegh-Guldberg and Williamson, 1999; Yahel et al., 2003). Rates of dissolved organic matter metabolism can be either significant or insignificant in the context of total metabolism. Much of the metabolism has been attributed to symbiotic bacteria (Ferrier-Pages et al., 1998; Yahel et al., 2003), but the cycling of dissolved organic matter at the community and ecosystem scales remains poorly understood. The metabolism of specific organic

compounds occurring in low concentrations, such as steroids, can have substantial impacts on the biology of specific organisms (Tarrant et al., 2004).

Reef waters also contain dissolved organic nitrogen; it is typically exported from reef communities (Wilkinson et al., 1984). The nature of dissolved organic nitrogen and the rate kinetics of its uptake are also unknown, making it difficult to establish their rates of uptake or recycling. Like dissolved organic compounds, generally, dissolved organic nitrogen may be resistant to chemical breakdown in seawater and require bacterial or sponge communities for re-mineralization; its uptake and release by the benthic community will thus strongly depend on the composition and abundance of the benthic biota.

### Fluxes of sediment carbon

Sediments in coral reefs typically contain  $<1\%$  organic carbon, indicating little sequestration of organic carbon into these systems. By contrast, rates of inorganic carbon deposition (as calcium carbonate skeletons) are large, its production accounting for approximately 10–20% of gross primary production. Communities with high gross primary production tend to have the highest calcification rates (Table 2). Calcification is positively correlated to light and net photosynthesis (Gattuso et al., 1999); the activation energy to produce a typical amount of calcium carbonate represents only 1% of the energy in gross primary production (activation energy for carbonate precipitation is  $\sim 4 \text{ kJoule m}^{-2} \text{ d}^{-1}$  for  $0.1 \text{ mol CaCO}_3 \text{ m}^{-2} \text{ d}^{-1}$ ). The rate of calcification is positively correlated to carbonate ion concentration in the sea water (Atkinson and Cuet, 2009); projected decreases in carbonate over the next 60 years from rising atmospheric carbon dioxide may reduce coral calcification by up to 30% (Smith and Buddemeier, 1992; Kleypas and Langdon, 2006). Dissolution of carbonates occurs naturally inside coral heads (Entsch et al., 1983), in interior pore-spaces of coral reef sediments (Tribble et al., 1990), and from the erosion action of boring organisms (Tribollet, 2008). Historically, rates of dissolution have been much slower than rates of biogenic precipitation ( $<10\%$ ; Tribble et al., 1990), but it is now suggested (Hoegh-Guldberg et al., 2007) that ocean acidification will reverse the relative rates.

### Pore-water carbon

Coral reef frameworks are partially lithified carbonate structures on which reef communities grow. Pore-waters of reef frameworks are mostly anoxic and contain elevated levels of dissolved nutrients (Sansone et al., 1990). This combination of low oxygen and high nutrients is a common feature of many coral reefs and a direct result of oxidation of organic matter in the interstitial spaces (Tribble et al., 1990). The subsequent production of carbonic acid from the oxidation of organic matter lowers pore-water pH and reduces the activity of the carbonate ion, thus facilitating *in situ* dissolution of carbonate (primarily aragonite). Reef pore-waters become anoxic at

depths of less than 1 m into the framework; however, some reef pore waters become anoxic within centimeters of the framework surface (Falter and Sansone, 2000b).

Hydraulically driven transport of water into, through, and out-of coral reef frameworks has long been hypothesized as the primary driver of framework diagenesis – the transformation of skeletal materials into limestone rock (Haberstroh and Sansone, 1999). It is proposed that the water brings both oxygen and particulate organic matter into the interstitial pore-spaces to sustain carbon metabolism (Huettel and Rusch, 2000). Coral reef frameworks are highly permeable, typically with hydraulic conductivities (K) ranging between 10 and 1,000 m day<sup>-1</sup>. Consequently, ambient hydraulic pressure gradients across coral reef frameworks do seem large enough to drive the flow of interstitial water (Falter and Sansone, 2000a) and thus drive diagenesis in the manner postulated. Wave-induced mixing is an important process controlling the exchange of shallow pore-water with overlying water (Falter and Sansone, 2000a). Thus, variations in the oxygen and pH structure of pore-waters within the top 2 m of sediment are affected by a habitat hydrodynamics, which is affected by its location on the reef and the direction of waves impinging on the reef. The deep anoxic regions of the reef frameworks, beyond the effects of wave-induced mixing, are high in methane and sulfate (Sansone et al., 1990).

## Summary

Ranges, means, and limits of carbon metabolism are summarized for coral reefs worldwide; zones and habitats of carbon production and consumption are also described. The underlying functional processes and parameterizations of those processes are discussed. At this time, however, there are gaps in knowledge, and it is particularly noted that interactions with nutrients are not yet well established.

Dissolved inorganic carbon (i.e., carbon dioxide gas, bicarbonate, and carbonate ion) is removed from the water column by autotrophs and fixed into organic (tissue and photosynthate) and inorganic (calcium carbonate skeletons) compounds. Gross primary production and community respiration rates vary greatly in different habitats of reefs, with much of the respiration of organic material occurring within the organism or the habitat in which it was produced. Net community production varies among habitats. In classic reef zonation, carbon from the fore-reef is exported to the back-reef area as detritus and dissolved organic carbon. Coral reef communities take up suspended planktonic organic matter at rates that are relatively low compared to their own primary production. Sediments in coral reefs typically contain <1% organic carbon, indicating little sequestration of organic carbon into these systems. Dissolution of calcium carbonate occurs naturally inside coral heads, in interior pore-spaces of coral reef sediments, and from the erosion action of boring organisms. Globally, the surface area of coral reefs is

small and thus coral reefs have negligible effect on the global carbon cycle.

## CARBONATE BUDGETS AND REEF FRAMEWORK ACCUMULATION

---

Chris T. Perry  
 Manchester Metropolitan University, Manchester, UK

### Definition

Carbonate budget: A quantitative measure, typically using census-based data, of the net rate of carbonate production within a given reef or carbonate sedimentary environment. The approach enables rates of reef carbonate production and erosion, associated with different biological, chemical and physical processes, to be quantified.

### Introduction

In many tropical reef environments, corals are important primary producers of calcium carbonate (CaCO<sub>3</sub>) and thus play a key role in reef framework construction. High percentage coral cover is often taken as indicative of a high rate of CaCO<sub>3</sub> accumulation and thus of rapid reef growth potential. However, corals represent just one of the carbonate producing groups that contribute to reef

construction. Carbonate is also added to a reef's structure by calcareous algae and other calcareous encrusting organisms, through carbonate sedimentation, and by the precipitation of marine cements. Alongside these constructive processes, a range of physical and biological processes also operate to directly erode the accumulating reef structure. This eroded carbonate may subsequently re-accumulate within the reef structure or be exported out of the reef system. Summing the rates at which these different carbonate producing and eroding processes operate, thus allows the net rate of carbonate production on a reef to be quantified. A carbonate budget is thus a summation of the inputs and outputs of carbonate within the active carbonate producing environment and is typically expressed as a measure in  $\text{kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$ . Carbonate budget assessments, although logistically complex to construct, thus provide a useful estimation of net carbonate production rates on a reef at a given point in time. They also provide a mechanism for quantifying the relative importance of different carbonate producing and eroding processes, and provide an important insight into inter-reef variations in styles and rates of reef framework development. This has relevance to understanding both variability in the composition of accumulating reef framework structures and actual rates of framework accumulation.

### Quantifying reef framework production and cycling

Coral reefs and reef sedimentary landforms are unique in that they are composed predominantly of calcium carbonate ( $\text{CaCO}_3$ ) that results almost entirely from ecological processes. Corals typically represent the primary constructional components on most reefs and can add significant amounts of carbonate per unit area of reef surface (Vecsei, 2004). However, other carbonate producing processes also add additional  $\text{CaCO}_3$  to the reef framework, the most important being by calcareous encrusters (especially crustose coralline algae), and the precipitation of syn- and early post-depositional cements (Perry and Hepburn, 2008). Significant amounts of primary carbonate are also produced in the form of sediment by other organisms or plants that induce  $\text{CaCO}_3$  deposition. These additional sources of carbonate can contribute significant quantities of carbonate to the reef structure and may actually dominate  $\text{CaCO}_3$  accumulation in specific reef settings (Bosence, 1984; Camoin et al., 2006).

A range of physical and biological erosional processes also influence rates and styles of reef framework accumulation. Bioerosion (the biological erosion of carbonate substrates) is facilitated by a wide range of reef-associated faunas, including species of fish and echinoids, and endolithic forms of sponges, bivalves and worms (see Chapter *Bioerosion*). These biological agents drive the direct degradation of both primary and secondary reef framework constituents and, as a by-product, may produce large amounts of sediment (Scoffin et al., 1980; Bruggemann et al., 1996). Physical disturbance, associated with storms and cyclones, is an important episodic process that influences reef framework development, largely

through the generation of coral rubble, the deposition of which is an important reef-building process in its own right (Hubbard, 1997; Blanchon et al., 1997), and through the export of reef-derived sediments (Hubbard et al., 1990).

These various carbonate producing and cycling processes may thus exert either a "constructive" or "destructive" (*sensu* Scoffin, 1992) influence on reef-related carbonate accumulation, and the relative importance of each, within a given reef system, controls net rates of carbonate accumulation. This concept is defined by the carbonate budget approach to conceptualizing and quantifying reef geomorphic performance and can be viewed as the sum of gross carbonate production from corals and calcareous encrusters, as well as sediment produced within or imported into the reef, less that lost through biological or physical erosion, dissolution or sediment export (Figure 1). The balance between these different inputs and outputs represents the net production rate of framework  $\text{CaCO}_3$  and can be expressed as:

$$\text{Net rate of framework CaCO}_3 \text{ production} = [(P_{\text{pf}} + P_{\text{sf}}) - P_{\text{e}}] + \text{Sed}_i$$

where

$P_{\text{pf}}$  = Primary framework carbonate production.

$P_{\text{sf}}$  = Secondary framework carbonate production.

$P_{\text{e}}$  = Primary and secondary framework carbonate lost to erosion.

$\text{Sed}_i$  = Sediment incorporated into the reef framework (includes both benthic carbonate sediment and by-products of framework erosion less that exported from the reef).

Several detailed studies have quantified net rates of carbonate production, using carbonate budgets approaches, at the reef system scale, and these including studies on Caribbean reefs in Barbados ( $4.48 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ yr}^{-1}$ ; Scoffin et al., 1980) and St. Croix ( $0.91 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ yr}^{-1}$ ; Hubbard et al., 1990), and in the Indo Pacific in Hawaii ( $0.89 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ yr}^{-1}$ ; Harney and Fletcher, 2003) and Indonesia (ranging from  $11.68$  to  $-7.6 \text{ kg CaCO}_3 \text{ m}^{-2} \text{ yr}^{-1}$ ; Edinger et al., 2000). Several studies have also utilized census-based budget approaches to quantify rates of sediment production within reef-related sedimentary environments. These include estimates of reef island sediment production (Hart and Kench, 2007), and epiphytic carbonate production in seagrass beds (Nelson and Ginsburg, 1986; Perry and Beavington-Penney, 2005). It is relevant to note that rates of carbonate production on shallow-water reefs have also previously been estimated using measures of alkalinity change in the waters overlying reefs (see Chapter *Density and Porosity: Influence on Reef Accretion Rates*). This approach provides an estimation of total carbonate production and early dissolution (Smith and Kinsey, 1976), and while resultant production estimates are in broad accord with the gross production estimates determined in process or census-based studies, it is not possible to quantify the production and erosion rates associated with individual organisms and/or processes. The approach thus has

**Carbonate Budgets and Reef Framework Accumulation, Figure 1** Schematic illustrating the main production (+ve) and erosional (–ve) processes that determine a reef's carbonate budget.

significant merit but provides a different suite of data to census-based studies and does not enable the relative importance of different producer/eroder groups to be quantified.

#### Variations in carbonate production at the reef system scale

One important aspect of considering reef carbonate production from a carbonate budget perspective is the ability to quantify inter-reef variations in styles of reef framework accumulation. Kleypas et al., (2001), for example, highlighted a range of conceptual reef states that directly relate to variations in relative rates of carbonate production, sediment import and export and framework erosion. These different states demonstrate how shifts in the relative importance of individual processes, associated with different types of reef-building environments or environmental conditions, can result in fundamentally different reef budgetary states and reef framework structures. Production-dominated reefs, for example, exhibit rates of *in situ* biological  $\text{CaCO}_3$  production far in excess of rates of carbonate degradation and thus the budget is positive. This state is consistent with the rapid vertical growth trajectories exhibited by “keep-up” or “catch-up” reefs during the Holocene sea-level rise. In contrast, import-dominated reefs contain a high proportion of sedimentary material that is often terrigenous in origin. These reefs also have positive budgets, and good examples include the reefs described from the inner-shelf areas of the Great Barrier Reef in Australia (Smithers and Larcombe, 2003), Thailand (Tudhope and Scoffin, 1994) and Mozambique (Perry, 2005). Bioerosion-dominated reefs exhibit negative budgets with primary and secondary carbonate production being exceeded by biological substrate degradation. Examples include areas of high carbonate turnover, such as the non-framebuilding coral communities described from Oman (Benzoni et al., 2003) and the Red Sea (Riegl and Piller, 2000). Similar erosion-dominated states may also arise where non-calcifying groups become dominant and rates of carbonate production are reduced. A good

example of this has been described from the reefs around Uva Island, offshore Panama (Eakin, 2001).

#### Carbonate budgets and long-term rates of reef framework accumulation

The conceptual budgetary states discussed above provide a framework for understanding the influence of carbonate production and erosion processes on reef accretion potential and framework fabric development at the system scale. In reality, however, framework types and their production rates are likely to vary markedly within different reef sub-environments (reef crest, shallow reef front, reef slope, etc.) depending upon the composition and abundance of coral species, species growth rates and, variations in the types and rates at which different productional and erosional processes operate. Perry (1999) illustrated spatial variations in the relative importance of these various processes and the resultant framework fabrics across a fringing reef system in north Jamaica, and these intra-reefal variations are also evident in budget assessments conducted in different areas of individual reef systems (Eakin, 1996). Over longer (millennial) timescales, these variations aggregate to determine net framework accumulation rates that are evident in many reef core records. Data available from many reefs on Australia's Great Barrier Reef demonstrate a relatively consistent relationship between facies type and net long-term accretion rates; highest rates ( $> 8 \text{ m ka}^{-1}$ ) occurring in branched coral facies, intermediate rates (typically  $< 5 \text{ m ka}^{-1}$ ) occurring in head coral facies, and the slowest rates ( $< 2 \text{ m ka}^{-1}$ ) occurring within algal crust facies (Hopley et al., 2007). These datasets also demonstrate marked changes in framework accretion rates during different phases of reef growth, with slow net accretion immediately following initiation, highest rates occurring as reefs accreted under rapidly rising sea levels, and slow or suppressed rates as reefs reach sea level. These variations reflect the carbonate production states and processes associated with different phases of reef development and

can thus be viewed as an interplay between community states (and thus net carbonate production rates) and sea-level position. It follows from this that different sea-level histories in different regions should be reflected in different accretion rate histories. For example, because Caribbean reefs have only recently reached present sea level (e.g., Toscano and Macintyre, 2003), the Late Holocene period has been characterised by vertical framework accretion and positive carbonate budgets. In contrast, sea levels in the Western Indo-Pacific region were attained ~6,000 years ago (with some reefs also then subjected to somewhat higher than present levels and subsequent sea-level fall e.g., Smithers et al., 2006). Thus in the Indo-Pacific, the Late Holocene period has been associated with dramatically reduced rates of carbonate production and vertical accretion (Hopley et al., 2007).

### Using carbonate budgets to monitor changes in reef "health"

As outlined above, the balance between processes producing  $\text{CaCO}_3$  and those removing it or converting it to sediment exerts an important influence on net rates of reef carbonate production and accumulation at a range of scales in time and space. Transitions in the rates at which any of the individual, or combined processes (either constructive or destructive) operate consequently have important implications for reef structures and reef-associated sedimentary landforms because they may shift the balance of the carbonate budget. Such changes may be driven either by direct anthropogenic activities (see Done, 1999; Hallock, 2001), or by climate-change induced shifts in sea level, temperature or seawater chemistry. All have the potential to modify the ecological functioning of reefs - changes that are

**Carbonate Budgets and Reef Framework Accumulation, Figure 2** (a) Ternary diagram showing different carbonate production states determined by variations in the relative importance of primary (coral) and secondary (calcareous encruster) carbonate production and carbonate breakdown to sediment/dissolution by bioerosion. Budget state points occupied by different reefs at the reef-wide scale (*closed circles*) and the reef sub-environment scale (*open circles*) where appropriate carbonate budget data exists are shown. (b) Conceptual model showing hypothetical transitions and potential pathways in reef carbonate production states driven by ecological or environmental change. Points A and A<sup>1</sup> are analogous to "production-dominated" reef states with production dominated by corals and calcareous encrusters, respectively. Point C is analogous to a "bioerosion-dominated" state. Subtle transitions in production status (e.g., A-A<sup>2</sup> and vice versa) may occur due to intermittent disturbance events where the relative importance of carbonate producers and/or the ratio of production to bioerosion changes, but the system is still one of positive net production. In some cases, reefs may shift from states of net accretion to net erosion (pathway A-B-C). Cessation of disturbance or an adaptation of the coral community (e.g., recruitment of, or replacement by, new, better adapted species) may allow transitions back to conditions of high carbonate production, with either similar (pathway C-B-A) or modified net production rates (C-B-A<sup>2</sup>). Adapted from Perry et al. (2008).

consistent with the “phase shift” concept (Done, 1992) – and thus to alter the carbonate depositional system. Such changes clearly demonstrate the potential for reef budget states to shift from positive (accretionary) to negative (erosional), a concept illustrated in recent studies of both anthropogenically impacted reefs in Indonesia (Edinger et al., 2000) and those impacted by El Nino-related sea-surface temperature fluctuations in the Eastern Pacific (Eakin 1996; 2001). In both cases, elevated rates of bioerosion have lead to shifts from positive to negative budgetary states, and emphasize the potential value, to reef health assessments, of quantifying budgetary components on coral reefs.

These concepts were recently developed by Perry et al. (2008) who proposed a framework production states approach that integrates assessments of the three key carbonate budget process groupings; primary production by coral, secondary production by calcareous encrusters, and bioerosion. The approach allows different states of reef production to be plotted within a ternary space (each process defining one corner of the ternary space; Figure 2a) and delineates areas of net accretion, net erosion, or accretionary stasis. One of the potential advantages of this approach is that it allows the relative importance of different process groups to be considered, thus acknowledging that while corals often dominate carbonate production, in some reef settings it is the calcareous encrusters (especially the coral-line algae) that make an equal or greater contribution to reef framework production. Similarly, appropriate consideration can be given to the role played by bioeroders in determining net carbonate production rates. This ternary approach also provides a useful mechanism for tracking temporal variations in the budgetary states of individual reefs, especially where ecological shifts (driven by either intrinsic or extrinsic factors) may modify the relative production rates or the abundances of carbonate producers/eroders (Figure 2b). This approach compliments the coral-macroalgal shifts identified within ecological reef phase shift models by encompassing transitions in carbonate production states resulting from different community states and disturbance regimes.

## Summary

A carbonate budget is a quantitative measure of the net rate of carbonate production on a reef (or within a carbonate sedimentary environment). The approach relies on census-based measures of the different producer and eroder groups on a reef – the individual measures of production and erosion being summed to determine net production rates per unit area of reef surface (typically expressed as a measure in  $\text{kg CaCO}_3 \text{ m}^{-2} \text{ year}^{-1}$ ). The use of carbonate budgets, although methodological complex, has considerable conceptual merit for understanding spatial and temporal variations in styles of reef framework development. Budgets also have considerable quantitative merit for determining production states at a given point in time and for tracking temporal shifts in carbonate productivity (e.g., production to erosion-dominated states) such

as may result from both intrinsically and extrinsically-driven environmental change.

## CARBONIFEROUS REEFS

Markus Aretz

Université de Toulouse (UPS), Toulouse, France

### Definition

All reefs, which formed during the Carboniferous period (ca. 359–299 Ma). The Carboniferous is the longest period of the Phanerozoic Eon. It was named after the abundance of Coal-bearing strata in its upper half.

Although the geological perspective has to be considered, the Carboniferous period shows considerable overlap to modern times. Reefs formed during times of profound global changes – greenhouse to icehouse climates, dramatically changed continent configuration during the process of supercontinent formation, and important and frequent sea level changes to name only a few of them. Timing and duration of reef development and their dimensions varied considerably on a regional scale, but on the global scale reefs developed throughout the entire Carboniferous period (Aretz and Vachard, 2007). Overall reef abundance was more common than what has been often postulated, but lower compared to peak times of reef development in the Middle Palaeozoic (Webb, 2002).

Characteristic is the lack of a stable reef community. A broad range of bioconstructors – microbial communities, calcareous and siliceous sponges, rugose and tabulate corals, bryozoans, brachiopods, and calcareous algae – contributed in varying abundances to different stage of reef development (as initiation, formation, stabilization, and domination). However, microbial communities were very abundant and crucial for many Carboniferous reefs.

Reefs occurred along a bathymetric gradient from the intertidal/subtidal interface to several hundred meters of depth. Very different reef types developed from small undifferentiated patch-reefs to atoll reefs on oceanic sea mounts to reef tracts along shelf margins. The scarcity of the latter had an important influence on the geometry of many Carboniferous shelf systems.

Individual reef development reflects the local and/or regional tectono-sedimentary environments, but climate seems to be the most important global driving force. Major re-organisations in the reef environments occurred at the base of the Carboniferous, around the Mid-Carboniferous boundary, and at the base of the latest Carboniferous.

The oldest reefs are shallow water microbial reefs near the base of the Carboniferous in Eastern Australia. Mud-dominated mounds and buildups often labeled as Waulsortian Mounds developed in deeper ramp settings of many tropical and subtropical shelf systems of Early Carboniferous age. Often they rose into the photic zone, which resulted in a marked biodiversity increase in the vertical profile of the individual mound. Contemporaneous reefs in shallow waters formed by the above mentioned

organisms in various abundances were wide spread in Gondwana, Laurussia, Armorica, Kazakhstan, China, and in the Panthalassa Ocean.

After climate cooling in the Mid-Carboniferous, corals did not contribute to reef formation any more. In the tropics and subtropics various calcareous algae (tubular algae, phylloid green algae and red algae) and chaetetid sponges contributed to the formation of three basic types. In somewhat more temperate waters pelmatozoans, bryozoans, brachiopods, and microbial communities were the main contributors to the formation of reefal/reef like structures (Wahlman, 2002).

In the latest Carboniferous period, following a short global warming, reefs of the tropical Tethyan realm consisted of calcareous algae and calcareous sponges, whereas in subtropical to temperate waters *Palaeoaplysina* mounds occurred in shallow settings and bryozoan-*Tubiphytes* reefs in deeper settings (Wahlman, 2002).

## CAY FORMATION

---

Peter Flood  
 University of New England, NSW, Armidale, Australia

### Definition

A cay (sometimes spelled key or quay) is a small, low elevation island composed of coral reef detritus of rubble or shingle and/or sand sized materials that have accumulated on the reef top surface.

### Formation

Cays are formed when ocean waves and tidal currents transport loose sediment across the reef top surface to a depositional node where concentration occurs and the sedimentary pile rises above the high tide (Hopley, 1981; Gourlay, 1988). Over time soil and vegetation may develop on the cay surface. This process is assisted by the presence of extensive sea bird populations and their associated guano deposition, which acts as a fertilizer for the developing vegetation.

There is a basic division of cays into windward shingle cays and leeward sand cays or mixed shingle/sand cays depending on the surface area and size of the associated reef top.

Stoddart and Steers (1977) seminal study of cays and the subsequent study by Stoddart et al. (1978), showed that cays on reefs of the Great Barrier Reef vary from small ephemeral sand patches emerging only at low tide to variable sizes of vegetated sand and shingle or mixed sand/shingle cays to the complex low wooded islands which are characterized by variable development of mangrove vegetation (McLean and Stoddart, 1978; Stoddart, 1965, 1969). The classification scheme of Stoddart and Steers (1977) is applicable throughout the various reef provinces (Indian Ocean, Maldives, Indonesia, Central Pacific Ocean, Fiji, Samoa, Polynesia, atolls; Atlantic Ocean, Caribbean, etc). One variant of the mixed sand/shingle cay type are called motus. This variety, unlike the sand-shingle cays that are molded by wave refraction, lie on unbroken reefs on atoll rims. They are formed by the deposition of shingle on the windward edge as storm boulder ridges. Such ridges serve as an anchor to further leeward deposition of sand-sized sediment (Nunn, 1994). Dickinson (2001; 2009) suggests that many of the Pacific Ocean motus are in fact “pinned” to the elevated abandoned reef flat which developed during higher-than-present sea levels during the mid-Holocene period.

Hopley et al. (2007, p.364, Fig. 10.16) have provided a summary of the attributes and frequency of reef types and cays on the Great Barrier Reef Province.

The cays are subjected to a range of physical, biological, and chemical variables that influence the morphological development (Flood, 1977, 1980, 1981, 1986; Umbgrove, 1947; Hopley, 1982, 1997; Chivas et al., 1986). Once the cay extends above the limit of high tide the wind action commences and the dry sands of the upper beach are transported inland to form dunes. This wind action produces an asymmetrical cross profile of the cay with a higher elevation on the windward side. Dunes of up to three meters elevation are not uncommon. Once colonized by pioneer vegetation and the presence of nesting colonies of sea birds, the humic and fertility content of the soil increases and larger vegetation such as shrubs and trees commence to grow. In addition, once the cay reaches a critical size, a fresh and/or brackish lens may become established towards the center of the cay.

The groundwater flow is usually radial from the core of the cay outward toward the beach (Vacher and Quinn, 1997). In the intertidal beach zone, interstitial seawater evaporates and calcium carbonate in the form of aragonite is deposited in the interparticulate pores of the beach sediments to form beachrock (Stoddart and Cann, 1965). Also, where large colonies of sea birds are resident over long periods their guano can cement and/or replace the cay sediments to produce phosphate rock or cay rock.

Serial changes in cay vegetation have been reported (Flood and Heatwole, 1986) as well as changes in their shape related to climatic fluctuations (Flood, 1986) and the impact of tropical cyclones (Flood and Jell, 1977; Scoffin, 1993; Verstappen, 1954; Woodroffe, 1993). There is considerable anxiety being expressed by those Indian Ocean and Pacific Island nation people who live on the low lying coral cays. They are concerned about the predicted climate changes and sea level rise (Woodroffe et al., 1990). Any sea level change will impact on the sediment source and the supply of sediment to and from the cay (Kench et al., 2005). Predicting the present and future stability is a challenging task for geomorphologists and engineers (Dickinson, 2001; 2009). Examples have been reported where the residual beach rock outcrops indicate the earlier presence of cays which were destroyed during hurricane/cyclone events.

The dates of Holocene sea level maximum for selected oceanic islands have been summarized by Nunn (1994) and Dickinson (2001) who found that in the millennia since 5,000 BP, no single scenario prevails and the observed patterns of sea level behavior vary depending on just where on the Earth the observations are made. This variability is related to the different properties and behaviors of the lithosphere.

## Summary

A cay is a supratidal feature developed on the reef top. It represents a stage in the evolutionary accumulation of reef derived detritus commencing as a subtidal bank, developing further as an intertidal bank, and then a supratidal island (unvegetated) to vegetated island (several steps in the complexity of vegetation).

A cay is the product of the interaction of the geological processes of sediment production, erosion, and transportation and the hydrodynamic process related to tidal processes and wave action (and cyclonic/typhoon/hurricane activities). Usually on oval or elongate platform reefs, the nodal point where the current/wave action energy decreases and sediment accumulates is situated on the reef top and not beyond the reef top in the area of the leeward sediment wedge.

The action of oceanic birds is of paramount importance in transporting seeds to colonize the surface of the cay; the dead vegetation adds to the humic deposits thereby enhancing the possibility of vegetation further colonizing the surface of the cay. Guano material also enhances the fertility of the soil profile, and around the beaches of the

cays beach rock, may form in the subsurface. On the larger cays, a freshwater/brackish water lens can develop and enhance the vegetative growth from shrubs to extensive forests of *Casuarina* and *Pisonia* trees.

## CHAMISSO, ADELBERT VON (1781–1838)

---

James Bowen  
 Southern Cross University, Lismore, NSW, Australia

By the end of the eighteenth century, investigation into the major problems of reef formation and the nature of coral “insects” had advanced considerably: the definitive investigations by Peysonnell resulted in general agreement that reefs were created in some way by minuscule polyps. Aboard the cruise of the *Adventure* to Tahiti by Cook was the German naturalist Johann Reinhold Forster (1729–1798) who distinguished a fundamental feature of atolls, namely that the formation of a circular structure enables the coral colonies to resist the rage and power of the ocean.

In the same period, once they gained control of the North Pacific with their ice-free port of Vladivostock, the Russians also became active. Of early significance were the findings of Adelbert von Chamisso, born in France and later settled in Berlin, the naturalist who sailed on the first voyage of the Russian ship *Rurik* in 1815–1818 under the command of Otto von Kotzebue

around the Pacific to the Hawaiian, Marshall and Mariana groups. In an account entitled “On the Coral Islands” in an appendix to Kotzebue’s narrative of the voyage, Chamisso made two important observations.

Firstly, he pointed out that corals thrive best in windward, turbulent reef fronts, stating that the larger species of corals, which form blocks measuring several fathoms in thickness, seem to prefer the more violent surf on the external edge of the reef a point amplified further on, that the windward side of the reef, exposed to the unremitting fury of the ocean, should first rise above the element that created it. His second observation attempted to explain why atolls appear in wide expanses of turbulent oceans, almost out of nowhere: because, he reasoned out, that the corals have founded their buildings on shoals in the sea; or to speak more correctly, on the tops of mountains lying under the water, and that, even further, variation in magnitude and distribution of atoll clusters probably depends on the size of the sub-marine mountain tops, on which their basis is founded.

Once back in Russia, Kotzebue published his findings in German in 1821 in three volumes under the general title *Reise um die Welt* (Voyage around the World), Chamisso writing much of the third volume, which became available to English geologists in a translation the same year.

## CLASSIFICATION OF CARBONATES

---

Christopher G. St. C. Kendall<sup>1</sup>, Peter Flood<sup>2</sup>

<sup>1</sup>University of South Carolina, Columbia, USA

<sup>2</sup>University of New England, Armidale, Australia

## Definition and introduction

Rocks are classified in order to communicate information about them. Limestone classifications are often intended to convey information about the composition and so, the depositional setting. All classifications of limestones tend to be rather arbitrary and they frequently overlap or do not fit one’s particular needs. Since binocular microscopes or hand lenses are the tools that are commonly available to the professional or academic geologist, a practical

classification should be based on descriptions that use these tools. When these instruments are used, it is usually possible to identify the individual grains forming the rock. Thus, most classifications require that the most significant sedimentary particle in the rock be described. For instance, if a rock is composed of ooids, it is termed an oolitic limestone. If the limestone also contains a minor element such as skeletal fragments, then it is called a skeletal-oolitic limestone.

Two of the most widely used classifications are those of Folk (1959, 1962) and Dunham (1962). Both classifications subdivide limestones primarily on the basis of their matrix content and their major component grains.

Most limestones are classified by Folk (1959, 1962) as allochemical rocks if they contain over 10% allochems (transported carbonate grains). Based on the percentage of interstitial material, the rocks may be further subdivided into two groups: sparry allochemical limestones (containing a sparry calcite cement of clear coarsely crystalline mosaic calcite crystals) and microcrystalline allochemical limestone (containing microcrystalline calcite mud, micrite, which is subtranslucent grayish or brownish particles less than about 5  $\mu\text{m}$  in size) (Figure 1). Further subdivision is based on the allochem ratios of Folk (1962) as is illustrated in Scholle and Ulmer-Scholle (2003) (Figure 2).

Thus, Folk's classification (Figures 1 and 2) is most suited for thin section study. Note that he terms rocks with appreciable matrix as micrites while matrix-free rocks that contain sparry calcite cement are termed sparites. Sparites and micrites are further subdivided on the basis of their most common grains.

In contrast, Dunham's classification (Figures 3 and 4) and its modification by Embry and Klovan (1971) and James (1984) update and illustrations deal with depositional texture. For this reason, Dunham's scheme is better suited for rock descriptions that employ a hand lens or binocular microscope. For example, if the grains of a limestone are touching one another and the sediment contains no mud, then the sediment is called a grainstone. If the carbonate is grain supported but contains a small percentage of mud, then it is known as a packstone. If the sediment is mud supported but contains more than 10% grains, then it is known as a wackestone, and if it contains less than 10% grains and is mud supported, it is known as a mudstone.

If one compares the two classifications, a rock rich in carbonate mud is termed a micrite by Folk and a mudstone or wackestone by Dunham. Moreover, a rock containing little matrix is termed a sparite by Folk and a grainstone or packstone by Dunham. The wide range of percentage of mud matrix that a carbonate may have and still be termed a packstone by Dunham sometimes reduces the utility of this classification. Embry has modified the classification of Dunham and Klovan (1971) to include coarse grained carbonates (above figure). In their revised scheme, a wackestone in which the grains are greater than 2 mm in size is termed a floatstone and a coarse grainstone is called a rudstone.

Both terms are extremely useful in the description of limestones. Embry and Klovan modified the boundstone classification of Dunham in order to graphically express the role that organisms performed during accumulation. They introduced terms such as bafflestone, bindstone, and framestone, which are useful in concept, but these can be extremely difficult to apply to ancient limestones where diagenesis and sample size can limit one's ability to determine an organism's function.

Other modifications followed Folk's (1965) recognition that though micrite is more commonly a product of sedimentary accumulation, it can also be cement, and/or a product of diagenesis. To this end, Reid et al. (1990) and Wright (1992) and others are not alone in reemphasizing the need to recognize the role of micrite and other allochems as a product of sedimentary matrix, internal cavity sedimentary fill, diagenesis, and cementation, and that some carbonate grains are the products of later diagenetic modifications. The reader is urged to recognize the multiplicity of origins of carbonates, though their sedimentary origin is commoner.

### A short history of limestone classifications

The classification of limestones has been constantly updated as new analytical techniques have been developed and new information has become available. This has resulted in new understandings about the origin and depositional setting of carbonate particles and carbonate sediments.

Limestone classifications underwent a rapid evolution shortly after Wolf (1961) published an excellent summary of the early classification schemes for carbonates. In this, he recognized that many of these classifications unfortunately were inefficient and commonly misleading; in particular, the descriptive terms used to describe carbonates included detrital, clastic, fragmental, granular, fossiliferous, calcarenite, coquina, etc. Each one of these terms conveys one particular aspect of information, but ignored, among other things, the presence or absence of cement or matrix.

Earlier classifications include Twenhoffel's of 1932 which recognized three major limestone groups:

1. Organic origin
2. Chemical origin
3. Mechanical origin

In the 1930s, workers differentiated between the following types of limestones:

1. Hard
2. Mud or soft

In the 1950s, workers recognized:

1. Uncemented
  - (a) Calcilutites (mud sized)
  - (b) Calcarenites (sand sized)
  - (c) Calcirudite (gravel sized)
  - (d) Mixture of (a), (b), and (c).
2. Primary hard (chemical or biochemically cemented)
3. Secondary hard (diagenetically modified)

C.G.St.C. Kendall, 2005 (after Folk 1959)

**Classification of Carbonates, Figure 1** Folk (1962) limestone classification table identifies the component (or allochemical) particles and whether the matrix is micrite or lime mud or a sparry calcite cement precipitated between the grains. Should intraclasts form >25% of the grains, then the rock is named an intraclastic limestone; if intraclasts are <25% and ooids are >25%, the rock is an oolitic limestone; if intraclasts and ooids are <25% each, then the rock is known as a biogenic, or skeletal, or pelletal limestone, according to the relative percentages of these allochemical grains. Limestones with multicomponents are named after these mixtures (e.g., a biopelsparite). A dismicrite is a micrite with spar-filled blebs (generally burrows) and a biolithite is a biologically bound rock.

In the late 1950s and early 1960s descriptions were based on size nomenclature, namely, calcilutite, calcarenite, and calcirudite. Others used calculite and calcisiltite for mud and silt sized, respectively. The work of Illing (1954), Folk (1959), Carozzi (1960), Dunham (1962), Embry and Klovan (1972), and James (1984) addressed these shortcomings and the two commonly accepted schemes that evolved from these are used today in industry

and academia. As explained above, these are based on the classification schemes of Folk (1962) and Dunham (1962).

Pettijohn (1952) divided limestones into two groups:

1. Autochthonous – formed in situ by biochemical processes
2. Allochthonous – consisting of transported and redeposited material.

**Classification of Carbonates, Figure 2** Folk's (1962) textural spectrum for carbonate sediments records 8 phases of sorting and rounding with the intent of capturing the deposition settings from low energy (*left*) to high energy (*right*). In very low-energy settings, micrites or mud-sized carbonate accumulate; in intermediate-energy settings, micrites with greater concentrations of allochemical particles, winnowed grain, and mud accumulations result; in high-energy settings, sorting and rounding of grains winnow most of the micrite matrix away. Textural inversions are the result of storm events that mix sediments from different settings or introduce short-lived conditions into a normally low-energy setting.

C. G. St. C. Kendall, 2005 (after Dunham, 1962, AAPG Memoir 1)

**Classification of Carbonates, Figure 3** Dunham's 1962 classification of carbonate rocks is intended to convey information related to their depositional setting. Carbonates that are supported by matrix (mud) or framework (grains) form the basis of this classification. The end members include noncrystalline limestones often characterized by referencing the major component grains.

Textural classification of reef limestones after Embry & Klovan (1971) and James (1984)

**Classification of Carbonates, Figure 4** Embry and Klovan (1971) modification of the Dunham's (1962) biologic classification of organically bound rocks. "Floatstone" replaces Dunham's "packstone"; the term "rudstone" replaces grain-supported biogenic limestones, and other organically bound rock are termed "bafflestone," "bindstone," or "framestone," depending on the character of the organic structures. These latter terms are often used to describe the fabric of reefs, bioherms, and other biogenic carbonates.

The Allochthonous grains are usually sourced intraformational or certainly intrabasinal.

The early researchers appreciated the complicated nature of carbonate rocks. They classified them both on the basis of origin of the components and depositional textures. Carozzi (1960) also offered a classification scheme which recognized several subtypes of Autochthonous and Allochthonous varieties of carbonates.

It was Folk (1959) who first successfully presented a comprehensive carbonate classification. He divided limestones into autochthonous, the so-called biolithites, and allochemical, those composed of various types of grains and matrix or cement. One or more grains can be associated with lime mud (= micrite) or lack micrite and instead are cemented by sparry calcite (= sparite). This classification has genetic implications and hence the conditions of the depositional setting and the formation of the grains are inferred. Interpretations about the depositional setting are of fundamental significance to oil/gas exploration and hence this classification scheme has gained wide acceptance.

Dunham (1962) proposed another classification scheme that is used as much as Folk (1959, 1962) by the oil/gas industry. Both classifications distinguish allochems, matrix or micrite, and sparry calcite cement and both schemes emphasize texture (depositional texture and hence depositional setting). Both are widely used today with some modifications (Embry and Klovan, 1971; James, 1984) to the virtual exclusion of all other limestone classification schemes. Many geologists use the two schemes interchangeably. Concurrently, micrite is recognized both as a sedimentary matrix, internal cavity sedimentary fill, and as a diagenetic product and cement, while some carbonate grains are the products of later diagenetic modifications (Reid et al., 1990; Wright, 1992).

#### Application of the recommended carbonate classification schemes

Irrespective of the classification scheme used (Folk or Dunham), the first question one should ask when classifying limestone is "can the deposition texture still be recognized?"

We recommend that a step-by-step approach be used in the Dunham scheme. The order of questions to be asked is:

1. Is the depositional texture recognizable?  
No – called crystalline limestone  
Yes – go to 2.
2. Was the rock bound together during deposition?  
Yes – boundstone  
No – go to 3.
3. Components deposited as distinct grains  
Grain supported – no mud – grainstone  
Grain supported – some mud – packstone  
Mud supported > 10% grains – wackestone  
Mud < 10% grains – mudstone

This classification key can be represented in a diagrammatic way (see Dunham Classification Scheme diagram).

### Summary

A variety of classification schemes have been proposed for limestones that provide information relating to their origin, component composition, grain size, presence of matrix or cement, and depositional setting. The first universally accepted scheme was that of Folk, developed in 1959 to integrate the origin, component composition, grain size, and depositional setting. This was elaborated further in 1962. Folk's scheme is most suited for the study of thin sections of limestones.

An alternative classification scheme was proposed by Dunham in 1962. This is more suited for limestone descriptions made when using a hand lens or binocular microscope. It was further modified in 1971 by Embry and Klovan. Dunham's scheme is now commonly used by the oil/gas exploration industry.

A subsequent modification was proposed by James in 1984. It enables these various earlier schemes to be used interchangeably. The classification schemes can be represented in diagrammatic form.

## CLIMATE CHANGE AND CORAL REEFS

Janice M. Lough

Australian Institute of Marine Science, Townsville, QLD, Australia

### Definition

Climate: Weather expected at given location and time of year, based on observations over at least 30 years, including average values and range of variability.

Climate change: Significant and persistent change in average and/or variability of climate.

Greenhouse gas: Constituent of atmosphere that absorbs and emits thermal infrared radiation.

Greenhouse effect: Trapping by atmospheric greenhouse gases of thermal infrared radiation, which otherwise would be lost to space, within climate system. Without the natural greenhouse effect, the earth would be about 30°C cooler and uninhabitable.

### A rapidly changing climate

Climate change is not new. Global and regional climate has varied and changed in the past on a range of time scales due to a variety of internal and external causes (IPCC, 2007a, Chap. 1). Organisms and ecosystems, such as coral reefs, have survived, changed their distribution, and adapted to many of these past changes.

We are, however, in a new era of rapidly changing global climate as a consequence of human activities. The evidence for increasing greenhouse gases due to burning of fossil fuels, land-use changes and agriculture activities since the late eighteenth century is unequivocal (IPCC, 2007a, Chap. 2). The atmospheric concentration of the main greenhouse gas, carbon dioxide (CO<sub>2</sub>), has risen about 40% from 280 ppm in 1750 to 383 ppm in 2007, the highest concentration of the last 650,000 years and possibly the last 20 million years. Not only

are atmospheric concentrations of greenhouse gases rising but also the rate of increase is accelerating (Canadell et al., 2007).

This increase in atmospheric greenhouse gases results in significant positive radiative forcing of the global climate system and global warming attributable to human activities. The most recent Intergovernmental Panel on Climate Change Fourth Assessment (IPCC-AR4) report provides observational and paleoclimatic evidence for significant recent warming of global climate that matches theoretical and modeled consequences of increased greenhouse gas concentrations (IPCC, 2007c). The relatively modest global warming observed to date has already been associated with changes in the global climate system such as more intense rainfall, more frequent droughts, sea-level rise, loss of Arctic sea ice, melting of land-based ice, and a widening of the tropical climate belt (IPCC, 2007a, Chap. 3; Seidel et al., 2007). The rate of warming is about twice as fast for land masses compared to oceans and for high latitudes of the Northern Hemisphere compared with that for low latitude regions. Observed changes in climate are driving changes in the world's biological and physical systems that are all consistent with a rapidly warming climate (IPCC, 2007b; Rosenzweig et al., 2008).

The observational record shows that the average global land and sea temperature climate of the most recent 30 years (1979–2008) is significantly warmer ( $+0.55^{\circ}\text{C}$ ) than the climate at the end of the nineteenth century (1871–1900; Figure 1a). The tropical oceans, home to the world's coral reefs, have also significantly warmed (at about 70% of the global average value) by  $+0.40^{\circ}\text{C}$  between the same periods (Figure 1b). The rate of warming has accelerated from  $0.05^{\circ}\text{C}$  (global) and  $0.04^{\circ}\text{C}$  per decade (tropical oceans), for the period 1871 to 2008, to  $0.12^{\circ}\text{C}$  (global) and  $0.08^{\circ}\text{C}$  per decade (tropical oceans) for the recent period 1950–2008.

Coral reef ecosystems, which occur in the naturally warm tropical oceans and are one of the largest sources of global marine diversity (Sala and Knowlton, 2006), are considered among the “most vulnerable ecosystems” to global climate change (IPCC, 2007b, Chap. 4, p. 214). This global-scale threat is occurring against a backdrop in which many of the world's coral reef ecosystems have already been degraded by direct human pressures. These local and regional stressors include overfishing, destructive fishing, and decline in water quality due to increased sediment, nutrient, and chemical pollution from changes in coastal land use (Hughes et al., 2003; Buddemeier et al., 2004). Fifteen years ago, a group of coral reef experts concluded that such “human pressures pose a far greater immediate threat to coral reefs than climate change, which may only threaten reefs in the distant future.” (Wilkinson and Buddemeier, 1994, p. VIII).

### Climate factors affecting coral reefs

#### Physical climatic environment of coral reefs: defining the envelope

To assess the consequences of change requires the understanding of present-day environmental controls on tropical

coral reefs (see also *Corals: Environmental Controls on Growth*). They are largely confined to shallow, warm, clear, and well-lit waters with  $18^{\circ}\text{C}$  identified as the minimum annual sea surface temperature (SST) necessary for reef growth and although upper thermal limits are less clear, nowhere, at present, is considered too warm for coral reef development (Achituv and Dubinsky, 1990). Comparing present-day distribution of nearly 1,000 reefs and a range of environmental variables, Kleypas et al. (1999a) found that the most important factors were warm SSTs (averaging  $27.6^{\circ}\text{C}$ ), high aragonite saturation (ranging from 3.28 to 4.06 and 3.83 marking the transition from coral reefs to non-reef-forming coral communities), and high available light. In general, present-day coral reefs live within a relatively narrow range of these three variables (Hoegh-Guldberg, 2005).

#### Other weather and climatic factors affecting coral reefs

Water temperatures, ocean chemistry, and available light thus broadly define, given suitable bathymetry, where coral reefs occur. Salinity and nutrient supplies are more regionally specific controls which are modulated by the amount of rainfall and freshwater flow into nearshore reef environments. Also regionally important are ocean circulation patterns that control larval supplies between reefs (connectivity) and upwelling of nutrients. Coral reefs span a range of environments from clear oceanic waters to low salinity and turbid waters near land (Fabricius, 2005).

Tropical cyclones (see *Tropical Cyclone/Hurricane*), the most destructive of the world's weather systems, are natural sources of disturbance to many coral reefs poleward of  $\sim 10^{\circ}$  from the equator (Emanuel, 2003). Tropical cyclones, through the large waves they generate, can directly affect and even decimate reef structures and coral assemblages as well as reducing salinity through heavy rainfall and causing coastal destruction associated with storm surges (Dollar, 1982; Massel and Done, 1993). Given time ( $\sim 10$ – $20$  years), and no other sources of environmental stress, coral reefs can recover from such local physical disturbances (Done, 1999; Hughes and Connell, 1999; Coles and Brown, 2007). In addition to the immediate physical impacts of tropical cyclones, their local occurrence has been shown in the Caribbean to have longer term consequences by limiting subsequent coral recruitment, survival, and compounding coral cover declines due to other factors (Gardner et al., 2005; Crabbe et al., 2008).

El Niño-Southern Oscillation (ENSO) events are the principle source of interannual global climate variability. This highly coupled ocean-atmosphere phenomenon is centered in the tropical Pacific producing significant climate and societal impacts throughout the tropics and some extratropical regions (McPhaden et al., 2006). ENSO fluctuates between two phases, El Niño and La Niña, each associated with distinct and different atmospheric and oceanic climate anomalies. From the perspective of coral reefs, the most significant of these anomalies are widespread warming of much of the tropical oceans during

**Climate Change and Coral Reefs, Figure 1** Annual anomalies (from 1961 to 1990 mean), 1871–2008 of (a) global average land and sea surface temperatures and (b) tropical average sea surface temperatures. *Thick line* is 10-year Gaussian filter emphasizing decadal variability. Linear regression line also provided (Data sources: HadCRUTV3, and HadISST2 <http://www.cru.uea.ac.uk>; Jones et al., 1999; Brohan et al., 2006; Rayner et al., 2003).

the evolution (typically over 12–18 months) of an El Niño event, as happened in 1982–1983 and 1997–1998. Both phases are also associated with changes in tropical rainfall amount and intensity (in particular floods and consequent increases in freshwater flows to nearshore reefs) and in preferred locations of tropical cyclone activity.

### Impacts of climate change on coral reefs

#### Warmer waters and coral bleaching

At the heart of tropical coral reefs is a mutually beneficial relationship between the coral animal and single-celled

photosynthetic plants. In return for protection and essential nutrients, the algae play a role in light-enhanced calcification and provide sufficient cheap energy to the coral host to allow rapid calcification and thus form the massive and complex carbonate structures of coral reefs (Barnes and Chalker, 1990; Veron, 2000). Coral bleaching describes the loss by the coral animal of all or some of these algae and their photosynthetic pigments so that the white calcium carbonate skeleton becomes visible through the translucent coral tissue. Coral bleaching is a response of the coral to an environmental stress such as unusually cold or warm temperatures, low salinity, or pollution.

Coral bleaching is not a new phenomenon due to global warming.

Corals live within 1–2°C of their upper thermal threshold, beyond which bleaching occurs (Coles et al., 1976; Jokiel and Coles, 1977). Currently maximum summer SSTs (the time of year when corals are most at risk from thermal stress) on coral reefs averages 29.5°C and ranges between 28.2 and 34.4°C (Kleypas et al., 1999a). There is not an absolute temperature at which corals bleach, rather (which is evidence of adaptation over the long term) the threshold varies with ambient SSTs (Berkelmans, 2002).

Observations off the Pacific coast of Panama in 1983 presented one of the earliest “most alarming” reports of “large-scale” bleaching of corals which was tentatively linked to the 1982–1983 El Niño (Glynn, 1983). Subsequent studies clearly linked these unusual events to warmer-than-usual SSTs (Brown, 1987; Glynn, 1996; Jokiel and Brown, 2004). What is new and now clearly associated with warming of the tropical oceans are mass coral bleaching events where entire reefs are affected and which can be locally attributed to unusually warm maximum SSTs (Smith and Buddemeier, 1992; Brown, 1997).

The real wake-up call regarding the sensitivity of corals to warmer waters was during the major El Niño event of 1997–1998 (McPhaden 1999) which coincided with the warmest year in global instrumental records (Hansen et al., 2006). Bleaching was reported from nearly every coral reef region and 16% of the world’s reefs was estimated to have been damaged (Wilkinson, 1998, 2004). The scale and magnitude of this event, during which impacts could be tracked round the world’s coral reefs as each reached its unusually warm seasonal SST maximum, catalyzed efforts both to understand and monitor conditions conducive to coral bleaching.

In an influential paper (Hoegh-Guldberg, 1999), mass coral bleaching events were firmly linked to warming of tropical seas as a result of climate change and, using global climate model (GCM) projections for selected locations, the author suggested that thermal thresholds for coral bleaching could be regularly exceeded within a matter of decades. Various studies have demonstrated that the level of thermal stress on coral reefs is closely linked to coral bleaching (e.g., Berkelmans et al., 2004) and that the level of this stress has been increasing as the tropical oceans warm (Lough, 2000; Barton and Casey, 2005; Sheppard and Rioja-Nieto 2005).

Several of the recent mass coral bleaching events have been associated with El Niño events (Williams and Bunkley-Williams, 1990). These do not cause coral bleaching but they increase the likelihood in many coral reef regions of thermal conditions conducive to coral bleaching (Lough, 2000; Eakin et al., 2009). Some reef locations, e.g., along the South Pacific Convergence Zone in the western tropical Pacific, are more likely to be unusually warm during the La Niña phase of ENSO [bleaching was observed here, e.g., during the 1998–1999 La Niña (Wilkinson, 2004)].

## Consequences of coral bleaching

A recent comprehensive review paper (Baker et al., 2008) summarizes much that we have learned and much that we still need to understand about the mass coral bleaching events that have affected many of the world’s coral reefs since the 1980s. As a consequence of bleaching, corals may fully recover, partially recover, or die, and there are a range of short- and long-term impacts on coral reef ecosystems. Examples include declines in abundance of coral- and reef-associated species, reduced coral growth rates, increased susceptibility of corals to diseases, enhanced rates of bioerosion, and impaired reproduction and recruitment.

The intensity and occurrence of coral bleaching associated with widespread thermal stress shows considerable variability. Bleaching is frequently more intense at the surface than on the sides of individual colonies, which implicates high light levels as a contributing factor (Salm and Coles, 2001; Brown and Dunne, 2008). Local weather conditions of slack winds, low cloud amount, and little water motion all favor both warming and increased light penetration through the water column. Different coral taxa show different thermal susceptibility, with branching corals often showing greater sensitivity than massive species (Marshall and Baird, 2000; McClanahan et al., 2004, 2005). Large-scale field surveys clearly demonstrate spatial clusters of more or less bleaching (Berkelmans et al., 2004; McClanahan et al., 2007a, b). Experimental studies suggest that high water motion can reduce the incidence of bleaching (Nakamura and Van Woesik, 2001; West and Salm, 2003; Smith and Birkeland, 2007). This is supported by field observations of reduced bleaching in regions of strong water motion due to tides, upwelling, mixing and wave energy (Salm and Coles, 2001; Skirving and Guinotte, 2001; Reigl, 2003), though in some locations high water flow has been suggested to reduce the corals ability to deal with thermal stress (McClanahan et al., 2005). Rapid cooling of SSTs by tropical cyclones can also locally reduce the occurrence and intensity of coral bleaching (Manzello et al., 2007).

Recovery from a bleaching disturbance is also variable across all spatial scales and across different coral reef communities (Golbuu et al., 2007; Baker et al., 2008). Some reefs recovered relatively rapidly from the catastrophic 1997–1998 event (e.g., Indian Ocean reefs), whereas others (e.g., Caribbean/western Atlantic reefs) continue to decline, due to ongoing local stressors. Lack of other local stressors is an important factor in determining how well coral reefs recover from bleaching (Sheppard et al., 2008). However, even with recovery of hard coral cover, there is evidence of differential recovery of various components of the original coral reef ecosystem, which results in a different community structure after the event (Smith et al., 2008). Key effects include loss of structural complexity and habitat, local extinctions, loss of biodiversity and key functional groups (Graham et al., 2006), and both immediate and long-term consequences

for corals themselves (McClanahan et al., 2009) and associated reef organisms (Pratchett et al., 2009).

An important question is to what extent corals and their symbionts maybe able to increase their tolerance to thermal stress with continued rapid global warming. Some argue that the potential for such successful adaptation on the time scales of observed and projected warming is limited (Hoegh-Guldberg, 1999, 2005). There is, however, experimental and observational evidence that some corals in some circumstances can and have increased their thermal tolerance by switching to a more thermally tolerant type of algal symbiont (Berkelmans and van Oppen, 2006; Goulet, 2006; Maynard et al., 2008; Oliver and Palumbi, 2009).

### Warmer water temperatures and coral diseases

Increased numbers of reports of diseases affecting marine organisms, including corals, have been tentatively linked to warming waters and El Niño events (Harvell et al., 1999). Coral disease outbreaks on the Great Barrier Reef (GBR) have been linked to temperature stress (Jones et al., 2004; Bruno et al., 2007), and experimental and observational studies show that coral black band disease is enhanced in warmer waters and high light conditions (Boyett et al., 2007).

### Warmer water temperatures: other effects

Warmer water temperatures can also directly affect physiological processes and distributions of corals and associated organisms. The northward range of two branching coral species has recently expanded in the western tropical Atlantic (Precht and Aronson, 2004). Coral community structure may change as juvenile corals grow more slowly and appear to die faster in warmer waters (Edmunds, 2004, 2007). Warmer temperatures have also been shown experimentally to affect larval supply, settlement, and survival (Negri et al., 2007; Nozawa and Harrison, 2007). Observational evidence of recent slowing in coral growth rates have also been linked to the combined effects of warmer waters and ocean acidification (De'ath et al., 2009; Tanzil et al., 2009).

### Changing ocean chemistry

A more insidious consequence, and potentially catastrophic (Veron, 2008), of increasing greenhouse gases for marine calcifying organisms is ocean acidification. About 30% of the extra CO<sub>2</sub> human activities have injected into the atmosphere has been absorbed by the oceans (Feely et al., 2004; Sabine et al., 2004) – if this had not happened, the earth would have warmed more than it has. Absorption of CO<sub>2</sub> lowers the pH, decreases the availability of carbonate ions, and this lowers the saturation state of the major shell and skeleton forming carbonate minerals (Kleypas et al., 2006). Observational and modeling evidence demonstrates ongoing decline in the aragonite saturation state of Caribbean waters over the period 1996–2006 (Gledhill et al., 2008). Lowering ocean

pH essentially shifts the balance of the geochemical equations whereby marine organisms, such as corals, calcify. Various modeling and experimental studies also demonstrate the reduced ability of corals to form their skeletal structures in more acidic waters (Kleypas et al., 1999b; Langdon and Atkinson, 2005; Orr et al., 2005; Doney et al., 2009).

Weaker coral reef structures reduce their structural resilience to the natural forces of erosion and a slower growth rate sets back recovery after disturbances. A recent experimental study suggests that ocean acidification can itself, and in combination with higher water temperatures, induce coral bleaching (Anthony et al., 2008). Ocean acidification affects not only corals (Guinotte and Fabry, 2008; Kuffner et al., 2008). Crustose coralline algae are particularly sensitive, and any setback to them may significantly undermine their vital role of cementing reef components together (Littler and Littler 1984; see also Chapter *Algae, Coralline*). The poorly cemented reefs of the eastern tropical Pacific (where aragonite saturation of waters is naturally low) may provide a picture of future coral reefs as the oceans continue to acidify (Manzello et al., 2008).

### Sea level

Global average sea level has risen by about 20 cm over the past century, primarily due to thermal expansion of the oceans and, to a lesser extent, melting of land and sea ice (IPCC, 2007a, Chap. 5), and the rate of rise has accelerated in recent decades (Church and White, 2006). Although continued rising sea levels are of significance for many densely populated, low-lying tropical communities adjacent to coral reefs (McGranham et al., 2007), a steady rise in sea level is not considered a major threat to present day coral reefs. Global sea level has been relatively stable for the past several thousand years and some reefs are limited by today's levels and the rates of rise are considered well within the ability of corals to keep up (Smith and Buddemeier, 1992; Done and Jones, 2006).

### Linking the physical environment with biological processes

Determining how coral reefs and associated organisms have and will respond to changing conditions depends upon good observational studies of both the physical environment and biological responses. Ocean climate clearly controls many aspects of coral reef ecosystems but even for the one of the best studied coral reef ecosystems, the Great Barrier Reef, our ability to determine the biotic responses of its many component organisms to climate, climate variation, and climate change is limited. The myriad organisms that make up a tropical coral reef such as microbial assemblages, plankton, macroalgae, seagrass beds, intertidal mangrove, salt marshes and wetlands, benthic invertebrates, sharks and rays, marine mammals, marine reptiles, fishes, and corals are variously sensitive to water characteristics (temperature, chemistry, and

nutrient supply), ocean circulation patterns, and extreme events such as tropical cyclones and freshwater flood plumes (see various chapters in Johnson and Marshall, 2007).

Although we have much better knowledge of the global distribution and health of coral reefs (<http://www.reefbase.org/main.aspx>), it is still difficult to clearly identify a significant increase in coral bleaching events due to confounding factors of greater awareness of the problem and hence more people looking for bleaching events (Oliver et al., 2009). Objective, large-scale methods are necessary for observing, for example, where and when bleaching occurs. These need to be supported by detailed and continuous local-scale observations that track coral reef mortality and recovery from such stress events (Spalding, 2009). It is also important to identify both bleaching-resistant (i.e., reduced impacts despite high thermal stress) and bleaching-resilient (i.e., rapid recovery after stress) coral reefs (McClanahan et al., 2007a). There have been dramatic improvements, through remote sensing, in our capabilities to observe coral reefs across large spatial scales but we still cannot routinely identify bleaching occurrences (Andreou et al., 2004; Elvidge et al., 2004; Mumby et al., 2004). Satellite-based observations since the 1980s have also dramatically improved our ability to detect anomalies in surface ocean climate, and a range of products, based on “oceanic hot-spots” (Goreau and Hayes, 1994), now routinely identify potential bleaching conditions in near real time (Eakin et al., 2009; <http://coralreefwatch.noaa.gov/>). Although such monitoring cannot prevent bleaching, it now allows scientists and reef managers to document the intensity, impacts, and recovery of reefs from such disturbances (see various chapters in Phinney et al., 2006; van Oppen and Lough, 2009).

## Projected future climates for coral reefs

### Predicting future climate

Several factors must be considered to understand and document the potential consequences and impacts of a rapidly changing climate. First, high-quality environmental observations are needed to determine the climatic envelope of particular organisms. Second, we need sufficient understanding of the complex physics of the global climate system, with the various interactions between the atmosphere, ocean, land, cryosphere, and biota, to realistically model current climate. Such GCMs then provide the basis for projecting future changes as a consequence of radiative forcing by greenhouse gases (IPCC, 2007a, Chap. 10). GCMs still, for example, have difficulties in correctly simulating certain components of tropical climate (Neale and Slingo, 2003; Reichler and Kim, 2008). The spatial resolution of GCMs is also relatively coarse which makes projecting to regional scales, most relevant to coral reefs, a challenge (IPCC, 2007a, Chaps. 8 and 11). Third, although based on the same physical laws, different GCMs vary in how they handle (parameterize) key

small-scale processes. This can lead to slightly different results both for present and future climate simulations but such parameterizations are necessary to keep computational costs down to manageable levels. There is, therefore, no single “perfect” GCM and the most recent IPCC-4AR uses multimodel averages of a large number of independent climate projections to account for inter-model variability (Pierce et al., 2009).

Finally, projecting future climates depends on predicting future greenhouse gas concentrations. These depend on a variety of socioeconomic factors that determine the global response and level of commitment to reduce and stabilize greenhouse gas emissions in the atmosphere (mitigation) and, hence, the magnitude and timing of future climate changes. The IPCC constructed a number of plausible scenarios to specify the concentrations of greenhouse gases as input to GCMs (Nakicenovic and Swart, 2000). These range from very carbon-intensive futures with high emission rates (750–800 ppm CO<sub>2</sub> by 2100) to scenarios where emissions are reigned in very quickly (450–500 ppm CO<sub>2</sub> by 2100). Many scientists consider that greenhouse gas reductions well below those of the low emissions scenario are necessary to avoid dangerous climate change (Hansen et al., 2008). We are currently tracking above the high emission scenario (Canadell et al., 2007; Raupach et al., 2007) and, without significant mitigation, we are committed to ongoing, rapid, possibly intensifying climate changes for the foreseeable future, and there is the specter of irreversible changes on the scale of thousands of years (Solomon et al., 2009). Reducing greenhouse gas emissions by 70% by 2100 would, however, halve the magnitude of temperature changes compared to the high emissions scenario and would confine warming of the tropical oceans to 0.5–1.0°C (Washington et al., 2009).

### Projected global changes

Average global temperatures are projected to be ~2–4°C warmer (1.1–6.4°C maximum range from different scenarios) by 2090–2099 compared to 1980–1999 and tropical SSTs are ~1–3°C warmer. An intensified hydrological cycle will increase rainfall in tropical high rainfall regions, reduce rainfall in the subtropics, and the intensity of rainfall extremes will increase. Ocean pH will decrease by 0.1–0.3 pH units. There may be fewer tropical cyclones, but those that do occur are likely to be more intense. It is unclear from global model projections as to what will happen to ENSO events but they are likely to continue as a significant source of interannual climate variability affecting coral reefs (IPCC 2007a, Chap. 10). A conservative estimate is that sea level will rise 20–60 cm by the end of this century, but this value underestimates the contribution of accelerated melting of land ice (Howat et al., 2007; Meier et al., 2007).

### A changing climate for coral reefs: future impacts

Several aspects of the current and ongoing changing climate are of significance for corals reefs, and the environmental

envelope they are used to with warming water temperatures and ocean acidification are likely to be most important (Kleypas et al., 2001; Fabricius et al., 2007; Hoegh-Guldberg et al., 2007; Lough, 2008):

- Warmer waters increasing incidence of coral bleaching and diseases; direct effects on physiological processes of corals and other reef organisms.
- Ocean acidification weakening skeletons and reef structures; direct effects on physiological processes of corals and other reef organisms.
- More intense tropical cyclones increasing incidence of localized reef destruction.
- More intense rainfall and river flow increasing frequency of low salinity waters that extend further offshore, stress corals osmotically, and raise ambient nutrient loadings, producing an environment that favors phytoplankton production, proliferation of macroalgae, increases in filter feeders, and Crown-of-Thorns outbreaks.
- Changed ocean circulation patterns affecting reef connectivity, upwelling, and nutrient supplies.
- Changes to ENSO activity (at present ill-defined) are likely to continue as source of significant interannual climate variability with El Niño events increasing probability of warmer waters throughout most of tropics and, therefore, conditions conducive to coral bleaching and coral diseases superimposed on warmer baseline water temperatures.
- Rising sea level may drown some deeper reefs, increase shallow areas available to others, and wash away low-lying reef islands and cays. Likely to increase destruction associated with more intense tropical cyclones due to higher storm surges and intensified coastal erosion.
- Combined effects of chronic acidification with increased frequency of disturbances to reefs (bleaching, tropical cyclones) and reduced recovery intervals between disturbances.
- Compromising of physical structure of reefs with an overall decline in building of calcium carbonate reef structures, a shift in balance from net calcification to net erosion, and an increased available bare substrate for algae.
- Loss of structural complexity will reduce the range of habitats and shelter available for other reef-associated organisms.

The net effects of this range of increasing chronic and acute stressors associated with a changing climate (combined with, in many locations, already degraded coral ecosystems) are likely to be much simpler and ecologically less complex coral reefs characterized by lower biodiversity. Coral reef “ecosystems” will not respond as a whole (Guinotte et al., 2003) and their regional makeup will change as some species are better able to cope while others become locally extinct (Graham, 2007; Carpenter et al., 2008) and some expand and others contract their current distributions. There will be direct physiological responses by taxa other than corals to

warming waters and ocean acidification. For example, experimental evidence suggests that future temperature and acidification scenarios will lead to reduced fitness and biodiversity losses in coral reef fishes (Munday et al., 2008; Przeslawski et al., 2008).

Several studies have considered aspects, singly and in combination, of these projected climate change impacts on coral reefs. Projections of future SSTs and aragonite saturation state of the Pacific Ocean for the late twenty-first century suggest that nearly all present-day coral reef habitats are likely to be marginal for reef development (though the projected changes are not outside the ranges of current marginal reef habitats). The potential for poleward migration of coral reefs (which depends on temperature, ocean chemistry, and suitable substrate) appears limited (Guinotte et al., 2003). The magnitude of future warming is likely to vary spatially with consequent spatial variability in future bleaching impacts and frequency (Sheppard, 2003; Sheppard and Rioja-Nieto, 2005; McClanahan et al., 2007b). Increases of only 1°C in Caribbean SSTs will expand the extent and intensity of bleaching events to 100% of the area (McWilliams et al., 2005). A similar increase on the Great Barrier Reef (GBR) would increase the occurrence of bleaching from the ~50% observed in 1998 and 2002 to ~80%, with increases of 2–3°C increasing the area of the GBR that bleaches to 97–100% (Berkelmans et al., 2004). Avoiding near-annual coral bleaching events within 30–50 years requires corals increase their thermal tolerance levels by 0.2–1.0°C per decade (Donner et al., 2005), and coral recovery may require management actions that reduce expansion of algae between disturbances (Wooldridge et al., 2005). Modeling studies also suggest that improving water quality through improved agricultural practices can significantly raise the thermal threshold for bleaching (Wooldridge, 2009).

Some studies have also attempted to identify the “tipping point” at which coral reefs can no longer sustain themselves as carbonate structures. Cao and Caldeira (2008) estimate that prior to the Industrial Revolution, 98% of coral reefs lived in waters with suitable carbonate chemistry, whereas once atmospheric CO<sub>2</sub> levels reach 450 ppm, only 8% of reefs will be in waters with the necessary aragonite saturation level. Dramatically, Hoegh-Guldberg et al. (2007, p. 1741) suggest that CO<sub>2</sub> levels greater than 500 ppm combined with water temperatures 2°C warmer will “reduce coral reef ecosystems to crumbling frameworks with few calcareous corals” and similarly that once CO<sub>2</sub> reaches 560 ppm “all coral reefs will cease to grow and start to dissolve” (Silverman et al., 2009, p. 1).

### Combined disturbances and recovery intervals

Long-term observational studies demonstrate the sensitivity of coral reef communities to repeated disturbances. Tropical cyclones, bleaching events, low salinity waters due to heavy rainfall and river flows, outbreaks of

diseases, and coral predators (such as Crown-of-Thorns starfish – see *Acanthaster Planci*) all have direct and flow-on effects to coral reef communities (Wilson et al., 2006; Riegl and Purkis, 2009). Impacts and recovery are variable and repeated disturbances with reduced intervals between them are likely to increasingly compromise the structural integrity and community makeup of these ecosystems (Done et al., 2007; Feary et al., 2007; Wakeford et al., 2008). Because of such multiple climate and local physical stressors on coral reefs, a more holistic modeling approach is required to projecting future status of coral reef ecosystems (Sarmineto et al., 2004).

### Potential actions

Drastic and immediate reductions of anthropogenic greenhouse gas emissions to the atmosphere are the first step to stabilizing global climate and the climatic environment of coral reefs. Coral reefs have been described as one of the “world’s failing ecosystems and one of the most persuasive examples of the effects of global environmental damage” (Downs et al., 2005, p. 486). What other actions, if any, can assist the maintenance of present-day coral reefs into the future? First, protection of these ecosystems from local direct stresses enhances their resilience and recovery from the additional stresses of climate change. This has led to many calls for greatly expanded networks of marine protected areas (Bellwood et al., 2004; Pandolfi et al., 2005; Mora et al., 2006; Wilson et al., 2006; Hughes et al., 2007). At all levels, it is the addition of humans into the equation of coral reefs that is causing the problems (Downs et al., 2005; Mora and Ginsburg, 2008) and it has been argued that we only lack the commitment to implement appropriate protection strategies (Sale, 2008). Second, it is clear that some coral reefs and parts of coral reefs are more resistant to climatic stresses such as bleaching and some are more resilient as demonstrated by relatively rapid recovery. Such reefs and locations within reefs are clear targets for enhanced protection (West and Salm, 2003; McClanahan et al., 2007a; Graham et al., 2007, 2008; Diaz-Pulido et al., 2009). Third, climate change and increased likelihood of significant disturbances need to be incorporated into selecting, designing, and managing marine protected areas (Baker et al., 2008; Game et al., 2008). Fourth, we need to improve early warning systems, seasonal climatic outlooks, and monitoring of physical and biological conditions on reefs (Weeks et al., 2008; Maynard et al., 2009; Spillman and Alves, 2009). Finally, we need improved GCMs for the tropics (Shukla et al., 2009) including better spatial resolution to allow better and more reliable predictions to be made for specific reef provinces (Donner et al., 2005, 2009).

### Summary

Coral reef ecosystems are highly vulnerable to stresses associated with a changing climate. These stresses are superimposed on local stresses in many regions that have

already resulted in significant degradation in the goods and services that healthy coral reefs provide (Buddemeier et al., 2004). Coral reefs are unlikely to disappear, but in the future they are likely to calcify less and there will be fewer reefs that are able to sustain the necessary reef framework that supports many thousands of marine organisms with a consequent loss in marine biodiversity (Guinotte et al., 2003). Our understanding of the full consequences of a rapidly changing climate and ocean chemistry for coral reef ecosystems is still limited and, unfortunately, the experiment is occurring in real time in the real world. The consequences of anthropogenic climate change for coral reefs are inequitable. The countries most responsible for anthropogenic climate change produce 6–11 times more CO<sub>2</sub> per person than the more than 400 million people living close to coral reefs (Donner and Potere, 2007). It is, however, these communities that will suffer most from the loss of the goods and services provided by healthy coral reef ecosystems.

## CLIMATE CHANGE: IMPACT OF SEA LEVEL RISE ON REEF FLAT ZONATION AND PRODUCTIVITY

---

David Hopley  
 James Cook University, Townsville, QLD, Australia

### Definitions

**Climate change:** projected changes to atmosphere and ocean which may affect coral reefs and their biota in a detrimental way, usually considered over the next 100 years or so.

**Sea level rise:** one of these projected changes resulting initially from thermal expansion of the oceans and longer term melting of glaciers, projected to be 13–68 cm by 2100.

**Reef flat:** the intertidal part of the coral reef, exposed at low tide, often sediment covered but with living corals in pools, for example as micro atolls, or around the lower edges of the reef flat where exposure is of shorter duration.

**Productivity:** the production of calcium carbonate forming the framework and sediments of the reef. Usually expressed as kilograms per square metre per year ( $\text{kg m}^{-2}/\text{year}$ ), the figure may be converted into reef accretion rates by taking into account the density and porosity of the contributing organisms and detrital facies.

### Introduction

The impact of sea level rise on coral reef flats was one of the first considerations raised in relation to climate change and coral reefs. Most publications in the 1980s considered the impact to be a beneficial one. This was especially so in the Indo-Pacific area, where isostatic adjustments had produced a sea level at or above its present position for over 6,000 years. Many reefs are now adjusted to this level with lagoons infilled, sediments dominating the reef flat and living corals limited to shallow pools (Figure 1). Such reef flats are too shallow for at least half the tidal cycle for the transmission of waves with sufficient energy to entrain and transport all but the finest sediments.

Many general references on Greenhouse effects emphasized the rejuvenation of reef tops (e.g., Henderson-Sellers and Blong, 1989) whilst others went as far as suggesting reefs could be drowned and many ecosystems eliminated (e.g., Falk and Brownlow, 1989). Some scientific assessments suggested that renewed coral growth would make reef flats aesthetically more pleasing (e.g., Hopley and Kinsey, 1988).

### Reef flat attributes and sea level rise

Atlantic reefs have experienced a continuous sea level rise throughout the Holocene (for isostatic reasons) with the result that their shallowest points are commonly subtidal and have a living coral cover. They are thus well placed to accelerate their growth as sea level rises. Indo-Pacific reefs, however, already at sea level for over 6,000 years, are very different. Many lagoons have been completely infilled (see *Reef Classification by Hopley (1982)*). Rather than living corals, shingle ridges and cemented platforms are to be found on the windward margins of many reefs and mangroves have colonized the sheltered areas behind them. The result is the typical low wooded island morphology found, for example, on the northern Great Barrier Reef (GBR). Reef flats are sediment covered often stabilized by binding organisms such as seagrass and macro algae. Corals, including micro atolls may be confined to moated parts of the reef flat.

Geomorphologically, these reef flats are inert for much of the time. As demonstrated by Kench and Brander (2006), at Warraber Island in Torres Strait (maximum tidal range ca. 4 m), Lady Elliott Island, in the southern GBR (1.7 m) and Cocos-Keeling atoll in the Indian Ocean, (1.2 m), both the high loss of energy of incident waves at

**Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity, Figure 1** Inert reef flat which has been at sea level for >5,000 years. Coconut (Poruma), Torres Strait.

the reef edge and long subaerial isolation at low tides are the reasons for their being insufficient energy for sediment movement. The Warraber reef flat is inactive for long periods, with waves above 0.05 m on the outer reef flat <30% of the time and 0.1 m only 19% of the time on each Spring to Neap cycle. “Energy windows”, when waves can perform geomorphic work, are determined by critical water depths which are exceeded between 16.2 and 38% of the time at the GBR sites. However, on Cocos-Keeling because it is open to oceanic swells and has a low tidal range, this time period can be up to 76% of the time, thus accommodating greater sediment movement.

### Reef flat response to sea level rise

Analyses of different scenarios of rates of sea level rise on the typical zones of reef flats and reef islands have been made by Hopley and Kinsey (1988); Hopley (1993); Hopley (1997); Hopley et al. (2007). Projections for 2100 by Hopley and Kinsey (1988) were up to 1.8 m, but by 1993, they were a more modest 30 cm to 1.0 m (average 60 cm), by 1997 23–96 cm and currently 13–68 cm (all figures from IPCC reports). Although the rate of annual sea level rise ranges from only 5 to 15 mm/year, this is important for reef flat ecology because it approximates the vertical growth rates of some of the slower growing corals. The realized value of sea-level rise will determine how much and how quickly vertical accommodation space is added, the places and heights that corals may grow, and the wave energy, currents and hence sediment transport on the reef flat (see *Accommodation Space*). Response in the form of vertical accretion can also be calculated. Estimates using alkalinity anomaly measurements (Kinsey, 1985), closely match those from the

geological record (Davies and Hopley, 1983). For the major ecological zones these vertical accretion rates are:

- 100% coral on hard substrates – modal rate of 7–8 mm/year but up to 15 mm/year for highly porous branching corals on a hard substrate.
- Algal pavement – 3–4 mm/year
- Reef flat sand and rubble – 0.4 mm/year

Using these figures Hopley and Kinsey (1988) suggested that reef flats would be completely rejuvenated in 100–150 years accreting initially at 4 mm/year then accelerating to 7 mm/year. Reef growth rates from dated cores indicate that all reefs would be drowned by a sea level rise >8–9 mm/year. For many inshore reefs of the GBR, rejuvenation would be aided by inundation of 1–1.5 m raised reef substrate dating from higher sea level stands of the mid-Holocene times.

By the mid-1990s sea level rise projections were more conservative (0.3–1.0 m, average 60 cm). Hopley (1997) modeled the impact of both the earlier rise of 1.8 m and a more modest 0.5 m on a typical atoll reef flat (from Bikini, Emery et al., 1954) (Figure 2). The higher rise resulted in the inundation of the entire reef flat by about 2070, the outer flat becoming entirely coral covered, producing sediment for the deepening lagoon and inner sand/rubble flat as wave transport became more efficient. In contrast the response to the slower rate of rise was a reef flat that more or less retained its original zonation. The inner flat may become shallowly submerged but even here transport of sediment from the windward margin may maintain its level at about LWM. Calculating the calcium carbonate production for a 1 m wide transect across the entire 70 m wide atoll reef flat produced a figure of 2,020 kg/year for the present time, and a similar

**Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity, Figure 2** Modeled atoll reef flat and response to a sea level rise of 0.5 and 1.8 m by, 2100 (from Hopley, 1997).

2,220 kg/year for the similar zonation in 2100 after a 0.5 m rise. After a rise of 1.8 m, by contrast (Figure 2), the carbonate production rate across the reef flat was 4,950 kg/year and the reef flat zonation highly modified with much of the active coral growth having moved shorewards.

Hopley et al. (2007) also undertook a similar exercise for a >3 km wide reef top typical of some GBR planar

reefs. Again, calcium carbonate productivity was increased only marginally by a rise in sea level of 0.5 m. However it was more than doubled by the larger rise as the reef top was rejuvenated. In both instances water levels would rise over the reef flat, laterally transporting much of the new material towards leeward cays, or lagoons. This would be especially so if a large proportion of the new growth

was in the form of fragile branching corals, small foraminifera or other easily transportable sediment components.

Some efficiency in sediment movement may be lost as the new reef top becomes rougher with new vertical relief in the form of coral spurs, storm rubble, etc. (Kench and Brander, 2006). Generally shallow lagoons are likely once more to become effective sediment sinks. In some circumstances, there may be a surplus that can contribute to island construction.

### Reef island responses

Initial climate change predictions described dire consequences for reef islands, as contours representing extreme high tide level were merely moved upward on island shores. However, researchers working directly on the physical processes on reefs (see Hopley et al., 2007 for discussion) generally agree that rising sea levels of the magnitude projected over the next 100 years will be far less damaging and will produce substantial reworking of surficial sediments enough to at least maintain the island mass. Island stability will be aided by a retaining effect of beach rock and other cemented materials. Additional transported sediments and higher water levels will allow cyclonic storms to more effectively emplace shingle ridges to motus, a very important part of the island building processes (e.g., Bayliss-Smith, 1988; Maragos et al., 1973). Sediment movement will also occur on a more regular basis. Kench and Brander's (2006) research on mesotidal Australian reefs indicated that sediment movement is currently restricted to less than 50% of the time. On Warraber Reef in Torres Strait (and other Indo-Pacific reefs) effective sediment movement ceased about 2,000 years ago but a rise in sea level of only 0.5 m may unlock stored sediments which will be moved towards an adjacent cay or motu.

Similar responses have been modeled on Raine Island (northern GBR) by Gourlay and Hacker (1996). They indicated that the height of the beach berm is determined by the run-up height of the dominant wave action – at highest Spring Tide. A berm elevation of 4 m could be built by small flat waves of 0.5 m height breaking directly onto a beach at a tide level as low as 2.3 m. They showed that a small rise in sea level without any corresponding build up of reef flat level would result in the attainment of greater berm height under most weather conditions, i.e., build-up of the island by an amount which would exceed the amount of increase in water level. On Raine Island they suggest that with a 0.6 m rise in sea level, larger 1.6 m waves would increase berm height by a factor of 0.8 m. Smaller waves of 0.5 m would increase the height by 1.2 m, i.e., berm height would increase from an initial 4.0 m to up to 5.2 m.

Whilst the island mass may remain as a habitat for plants and animals it will be highly disturbed. Deposition on one part of the shore will be matched by erosion elsewhere as both prevailing wind directions and storm frequencies add to the impacts of sea level rise. Reworking of older parts of the island may remove a high proportion

of the mature organic soils and vegetation which form the most favorable habitat including as agricultural land for human populations. For migratory species such as seabirds and turtles, the reworked island may for a time, still provide a valuable resource but for permanent residents, coral reef cays may quickly become uninhabitable.

### Other factors influencing reef flat change

The start of this entry presented the optimistic view that coral reefs may be one of the few ecosystems to benefit from sea level rise. The discussion that followed suggested the optimism may be well founded in the light of renewed upward growth, changed wave action and increased sediment movement. However, sea level rise is not the only factor in climate change. Whilst increased cyclone activity may help add new ridges to reef islands, other environmental changes such as temperature rise and ocean acidification will have detrimental affects resulting in widespread coral mortality.

Sheppard et al. (2005) have described the results of coral bleaching in reefs of the Seychelles. Prior to the 1998 event fringing reefs had an outer veneer of 0.5 m high thickets of staghorn corals and massive *Porites*. Stripping of this veneer reduced reef roughness and created a pseudo sea level rise that was superimposed over a regional rise of ca. 5 mm/year. Sheppard et al. modeled the reef flat conditions of 1994, 2004 and 2014 concluding that the rate of erosion of Seychelles beaches would double in the next 10 years.

These figures are of great concern for many of the world's reefs subjected to rising sea level. However, reef disintegration as described for the Seychelles may not be nearly as rapid elsewhere, determined largely by the composition of the reef flat corals. Reef flat surfaces subject to a small fall in sea level remain within the energetic wave zone as well as the intertidal zone of highly active bioerosion. Where branching corals dominate the reef flat, stripping and pseudo-sea level rise may impact on the adjacent shore, as in the Seychelles. However, where massive or encrusting corals are dominant even though they may die in response to environmental change, they may not be removed, but stay *in situ* on the reef flat for 5,000 years or more, as illustrated by Hayman Island in the central GBR (Kan et al. 1997). Here a pseudo sea level rise is not superimposed on regional sea level behavior.

### Summary

Responses of reef flats to sea level rise in the twenty-first century will likely be many and varied. The response in each case will depend on specific reef characteristics and environmental setting: the existing height of the reef relative to sea level; the local tidal range and rate of sea-level rise; the existing composition and zonation of coral assemblages, and hence susceptibility to the exacerbating effect of pseudo sea-level rise; the changing ecology with changed environmental conditions and disturbance regimes; and propensity for old and new sediments to be transported by wave action.

The only generalization is that the response of coral reefs will not be the same in all locations.

## CLIMATE CHANGE: IMPACT ON CORAL REEF COASTS

Charles Sheppard

University of Warwick, Coventry, UK

### Definition

Climate change is impacting directly on coral reef coasts. When warm spikes, superimposed on a long-term gradual warming trend, cause massive mortality of corals, the elevation of the shallow reef relative to the shore is lowered, thereby increasing the wave energy that reaches the shore and the consequent erosion of low lying shores.

### Introduction

A primary service supplied by coral reefs to the human communities which live near them is that of shoreline protection. Infrastructure and settlements occur along the shorelines of many hundreds of atolls, as well as along thousands of kilometers of shoreline of high islands. They are all protected to a considerable extent by the breakwater effect provided by coral reefs that fringe those shores. The reef's service in this respect is invaluable, but quantification of the effects and costs caused by their degradation lags well behind many of the better studied biological effects. Much of what we do know derives from engineering models.

The main impacts are caused by increases in the amount of wave energy which strikes the shoreline when the adjacent reef deteriorates, and when its elevation drops relative to sea level. In the recent past, this form of deterioration has come mainly from coral extraction to obtain limestone for building purposes, and from coral mortality caused by diseases. Now, and in the foreseeable future, it will be compounded by effects of global warming.

Traditional extraction of corals for use as building material, both as whole colonies or as excavated blocks of reef, has occurred for centuries. Perhaps the best known example of this has taken place in the Maldives, where the lack until recently of any significant quantity of alternative building material has meant that the reef flats around several settlements, especially the capital Malé, have been severely excavated. There are no good estimates of quantities taken, but it seems likely that around Malé the reef flat appears to have been excavated by local people to such an extent that they have lowered its elevation relative to sea level by at least half a meter.

Coral mortality from disease has especially affected the elevation of reef crests in the Caribbean. Until the 1980s the shallowest zone of corals comprised Elkhorn coral, *Acropora palmata* (Geister, 1977). This species grows upward to reach the low water mark in very dense thickets of over 2 m tall, even protruding above the water at low tides. However, over much of the Caribbean, these shallow water reefs have now disintegrated almost completely.

Enormous stands of very solid limestone colonies that packed the zone from the surface to about 4 m depth have been almost totally eliminated by disease (Rosenberg and Loya, 2004). As a result, affected reefs no longer contain a wave break reaching the low water level. Instead, this zone now consists of disintegrating rubble, remnants of the once-living branching coral, with a completely different ecological character. The areas are extensive: Figure 1 is an example from the island of Anguilla, where the extensive shallow, dead reef was previously a healthy *Acropora palmata* zone.

Sea water warming – the third cause of wide-scale erosion of coral reefs – is increasing in importance. Warm spikes, superimposed on a long-term gradual warming trend, have caused massive mortality of corals in many parts of the world. In the context of shoreline protection, the significant mortality is that of the very shallow corals on reef crests and reef flats. It results in a drop in the elevation of the corals, followed by a corresponding drop in the ability of the reef to absorb wave energy, and a consequent increase in the amount of wave energy that reaches the shore.

### Quantification of the problem: a case study

The effectiveness of the “breakwater” role of reefs is well known in general principle and assumed to be substantial, but has been poorly measured and is difficult to predict. However an example from the Seychelles (Sheppard et al., 2005) has estimated approximate magnitudes. There, concern was expressed about several areas of apparently increased shoreline erosion as well as a smaller number of areas where substantial pulses of sand had been pushed onshore over coastal roads. In 1998, warming in the central granitic islands had caused substantial coral mortality which was not recovering to any significant degree; indeed the reefs appeared to be slowly disintegrating. Prior to the late 1990s, the fringing reefs around the granitic islands had supported a complex ecology, including rich growths of corals. Luxuriant reef flats extended seaward from the sandy coasts of the islands to the reef face, or drop-off. These reef flats supported dense stands of corals (along with patches of seagrass, sand, and rubble) which grew up from the reef flats to the surface of the water at low tide (Figure 2). The horizontal, solid platform of the reef flat on which these corals grew is located

**Climate Change: Impact On Coral Reef Coasts, Figure 1** Simplified section of a Geographical Information System map of Anguilla, Eastern Caribbean, showing distribution of dead Elkhorn reef. Map is approximately 500 m<sup>2</sup>. The *mid gray color* (see key) was probably all Elkhorn before being killed before the 1980s. Further, the darkest gray (bare rock with algae) may also have been Elkhorn but has decayed through erosion sufficiently so as not to be recognisable as such. *Pale gray* is reef dominated by soft corals (*Gorgonacea*) but with some limited quantities of the reef building *Montastraea* coral. White is various mixtures of seagrass and sandy substrate with some seagrass.

**Climate Change: Impact On Coral Reef Coasts,**  
**Figure 2** Fringing reef of Praslin Island, Seychelles. Reef flat is 205 m wide, on calm day with small waves breaking at the edge of the reef flat. Dark patches underwater are seagrasses to shoreward and dead coral further seaward.

**Climate Change: Impact On Coral Reef Coasts,**  
**Figure 3** Underwater photograph (2004) of the profile of one of the reefs (off the main island), showing *Acropora* stand which had been dead for about 6 years and which has been progressively disintegrating. Top arrow represents distance between low water and the top of the reducing coral stand, lower arrow represents the distance between the 2004 upper surface of the coral stand and the plane of the reef flat.

generally 1–2 m below low tide. Typically, perhaps half of any single reef flat was covered by tall branching corals which, by the early 2000s, were dead and slowly disintegrating (Figure 3), with the result that the upper surface of the coral stands was eroding and dropping relative to sea level (Figure 4).

Wave set up, transformation, and propagation to the shore on coral reefs have been researched by Gourlay

and colleagues (Gourlay, 1994, 1996a, b, 1997; Gourlay and Colleter, 2005; Massel and Gourlay, 2000), based on both laboratory experiments and field measurements (Hardy et al., 1990; Hardy and Young, 1996). Important factors include the width of the reef flat; the proportion of the reef flat covered by corals; the depth in calm water conditions of both the tops of the coral stands and their base relative to the platform and sea level; and the height of the coral stand (pre- and post-mortality and collapse). Equations can be derived to predict the wave-forced, raised water level on reef flats resulting from wave breaking. This in turn depends on offshore wave height and period, and the decay of energy from reef edge to shoreline. Sea level rise may be factored in, as well as rounding and smoothing of the reef crest and reef flat as corals die and disintegrate.

In the Seychelles study it was found that the main driver of change in wave energy reaching shores was the “pseudo-sea level rise” created by increased depth resulting from disintegration of coral colonies. An additional factor was a reduction in rugosity as irregular and rough coral colonies slowly became converted to a smoother plane. Also taken into account was the proportion of each section of reef flat that was covered by corals (areas covered by seagrass or sand were treated differently by assuming either no change or by assuming that seagrass beds can grow vertically in response to changing water levels). In a before and after comparison (all coral stands reaching the low water surface compared to complete disintegration of the corals) the reduced roughness and greater depth resulted in much greater wave energy reaching the shore (Figure 5). Mitigating against the rising energy reaching the shore to some degree was coral mortality at the reef crest. Disintegration of these corals rounded off the reef in that area, affecting the initial wave set-up, in some cases changing reef morphology so that formerly distinctive reef flat, crest, and slope became blended together over a near-indistinguishable boundary. Reef flats with partial disintegration of previously abundant corals permitted about 20–60% more energy to strike the shoreline, whereas total disintegration permitted an additional 75% energy. An average 7–8% reached the shore before the mass coral mortality, about 11% in 2004, and a predicted 18% will reach the shore when coral attrition is complete. The sequence of events included an initial pulse of sand being created as corals initially died (in 1998), after which it, and the sand on the beach, was removed in an extended erosion phase.

There appear to be no quantitative data for other shoreline areas protected by coral reefs, though the effect is becoming commonplace, with shoreline attrition, especially on many coral atolls, being meters or tens of meters (Figure 6).

## Summary

A case study conducted in the Seychelles is described, in which it was estimated that the demise of the shallow

**Climate Change: Impact On Coral Reef Coasts, Figure 6** Example of recent shoreline erosion on a coral atoll (Chagos archipelago, Indian Ocean). The dead palm trees are now in the low intertidal zone and show that the land extended considerably to the left of their position - in fact to the exposed ridge on the left of the photo. Horizontal land loss here has been 20–30 m. (Photo Anne Sheppard.)

corals has and will result in an approximate doubling of wave energy striking the previously protected shorelines. This has resulted in substantial erosion with a high cost to the local population.

There are many anecdotal stories of shoreline erosion from around the world, especially around atolls. It is likely that a proportion of them are exaggerated or that the observations made are merely reflecting seasonal changes; it is well known that sandy shorelines behind coral reefs can change by tens of meters or even more on a seasonal basis. However, it is usually not too difficult to distinguish between seasonal changes and unidirectional or progressive changes that have progressed for several years, if only because the latter soon begins to show erosion of previously stable and long-lived shoreline vegetation (Figure 6), and then erosion of built infrastructure. Nevertheless the poor signal-to-noise ratio in matters of shoreline movement is a serious problem, making it difficult, in some cases, to distinguish between the seasonal and storm-driven noise in the system and any underlying, serious progressive trend that may be occurring. What is clear is that all forms of coral damage, whether from local, direct impacts, or from climate change, will reduce the effectiveness of the break-water effect provided by living coral reefs. Furthermore, in some cases, changes seen to date will be very much less than those predicted for the near future if temperatures continue to rise and if polluting discharges and mechanical extraction continue to reduce the abundance and resilience of coral reefs that fringe shorelines.

## CLIMATE CHANGE: INCREASING STORM ACTIVITY

---

Joshua Madin  
 Macquarie University, NSW, Sydney, Australia

## Synonyms

Increasing ecological disturbance; Increasing tropical cyclone (hurricane, typhoon) frequency and intensity

## Definition

An increase in the intensity and/or frequency of storms relative to a predefined expectation (e.g., historic yearly average or quantile).

## Introduction

Increasing storm activity is a hypothesized consequence of climate change that results predominantly from warming sea surface temperatures (SST). Significant scientific debate revolves around whether or not the storm activity is increasing and, if so, whether any increases are a consequence of global warming. This debate exists primarily because detecting such trends depends on the temporal and spatial scales examined, the duration and quality of available meteorological records, and the kinds of statistical and mathematical approaches used in analyses. Storms temporarily alter the physical state of coral reefs in a number of direct and indirect ways (see [Tropical Cyclone/Hurricane](#)). Direct examples include changes in

salinity (via rainfall) and impinging wave climate (via wind). Indirect examples include increased terrestrial runoff and associated changes in turbidity, chemistry, and human-induced pollution levels. By altering the physical state of ecological communities, storms are an important form of ecological disturbance that significantly shape ecological systems and are hypothesized to be at least partially responsible for the levels of species diversity. Increasing storm activity will drive changes in the biological and physical structure of coral reefs, and in turn the ecology of organisms that rely on the reef habitat for shelter. Although some studies have forged mechanistic links between storm activity and coral reef vulnerability, the impacts of increasing storm activity on coral reef ecology and physical structure of reefs remain largely unknown ([Figure 1](#)).

## Evidence

Theory suggests that tropical storm activity should increase with global mean temperature as warmer seas fuel tropical storm generation (Emanuel, 1991). While growing evidence strongly suggests that SST is increasing in tropical seas (see [Temperature Change: Bleaching](#)), evidence for increasing storm activity is less clear cut. Part of the reason for this uncertainty is that storm activity is comprised of two components that must be considered simultaneously: storm intensity and storm frequency ([Figure 2](#)). In general, more intense storms are less frequent (e.g., yearly cyclones) and less intense storms are more frequent (e.g., daily to weekly squalls). An increase in storm activity would theoretically shift this relationship upward (illustrated by the arrow in [Figure 2](#)). Such a shift can be interpreted in two ways. First, storms of a given intensity would increase in frequency within a given time period (A to A', [Figure 2](#); e.g., an increase in the number of category 3 cyclones each year). Second, storms of a given frequency would increase in intensity (B to B', [Figure 2](#); e.g., the largest yearly storm is more intense on average).

Early attempts to detect changes in storm activity focused on frequency and uncovered no clear trends. In fact, a more recent modeling effort suggests that Atlantic tropical storm frequencies might even decrease under future greenhouse-gas-induced warming (Knutson et al., 2008). Despite possible decreases in storm frequencies, studies (including Knutson et al., 2008) have shown that storm intensity is increasing. For instance, Emanuel (2005) looked at storm power dissipation (a measure of the total energy generated by a storm) and found it to be highly correlated with temperature, reflecting global warming. These results appear paradoxical according to [Figure 2](#): how can tropical storm intensity increase but yearly frequency decrease or stay unchanged? The answer becomes apparent when looking at the distributions and extremes of yearly storm intensities rather than averages (Gaines and Denny, 1993). In a study looking at the maximum wind speeds generated by tropical cyclones, Elsner

**Climate Change: Increasing Storm Activity, Figure 1** Cyclone Larry crosses the Great Barrier Reef, Australia, in 2006 (MTSAT-1R: Satellite image originally processed by the Bureau of Meteorology from the geostationary satellite MTSAT-1R operated by the Japan Meteorological Agency).

**Climate Change: Increasing Storm Activity, Figure 2** A schematic of the general inverse relationship (*bottom solid line*) between storm intensity and frequency, the two components of storm activity. Increasing storm activity would result in the relationship moving outwards (*top solid line*). See text for details.

et al. (2008) show that, while there is no trend in frequency nor the average maximum wind speed of yearly cyclones, the upper quantiles of maximum wind speeds indeed increase from year to year. That is, in each year a similar number of tropical storms reach “cyclonic” status and the maximum wind speeds generated by storms are similar on average; however, the maximum winds speeds of the largest storms are increasing. Simulations by Knutson and Robert (2004) support this idea, finding that warming induced by greenhouse gas entrapment may lead to increasing occurrence of highly destructive category 5 storms. Furthermore, Hoyos et al. (2006) link the increasing trend in number of category 4 and 5 hurricanes for the

period 1970–2004 directly to the trend in sea surface temperatures. However, Emanuel et al. (2008) concludes in a reanalysis of data from his 2005 study that the increase in power dissipation in recent decades cannot be completely attributed to global warming.

In summary, despite the growing evidence that the distribution of tropical storm intensities per year has stretched upward, the link between increasing storm activity and global warming remains unclear. The World Meteorological Organization (2006) state in a press release that “though there is evidence both for and against the existence of a detectable anthropogenic signal in the tropical cyclone climate record to date, no firm conclusion can be made on this point” and that “no individual tropical cyclone can be directly attributed to climate change.”

### Conclusions: consequences for coral reefs

Storms have a number of direct and indirect effects on coral reefs. Direct effects include mechanical damage and sedimentation to corals and reef structures by waves, storm surges, and currents, as well as lowered salinity by torrential rainfall (Woodley et al., 1981; Massel and Done, 1993; Madin and Connolly, 2006; Fabricius et al., 2008). Indirect effects include pollution and sedimentation caused by terrestrial runoff (Fabricius, 2005). Storms also have sub-lethal effects on the reef-building corals, such as physiological stresses that can lead to decreased growth, competitive ability, and reproduction as well as increased susceptibility to disease and bleaching.

One way to conceptually illustrate the influence of increasing storm activity on coral reef biodiversity is via

the Intermediate Disturbance Hypothesis (IDH; Connell, 1978). According to this hypothesis, a patch of reef that is exposed to mild and/or infrequent disturbances is likely to become dominated by one or a few species (the stronger competitors), resulting in low species diversity (point A in Figure 3) because these low-level storms rarely remove the dominant corals to create an empty space for new species to settle. On the other hand, very few species are able to survive extreme and/or frequent disturbance events, such as unusually high wave forces, bombardment and scouring by waterborne objects, and/or lowered salinity, also resulting in low species diversity (point B, Figure 3). As a result, species diversity tends to be highest on average at some intermediate disturbance level (e.g., near point C, Figure 3).

Assuming that the IDH provides a reasonable approximation for the relationship between the storm-induced disturbances and coral diversity, then increasing storm activity will affect the diversity of different reefs in different ways. For example, diversity might be expected to *increase* in benign reef patches that currently have low levels of diversity due to recent history of low disturbance (A to A', Figure 3). Conversely, diversity is expected to *decrease* on those portions of reef patches that currently have high diversity due to a recent history of intermediate disturbance (C to C', Figure 3). In order to make predictions about how reefs might change if storm activity were to increase, Madin et al. (2008) use an engineering model to measure the mechanical vulnerability of different colony shapes to storms. They show that, if storm activity increases and/or ocean acidification weakens carbonate structure (see *Ocean Acidification, Effects on Calcification*), future reefs will have fewer corals and be dominated by small and simple forms, which will in turn support lower levels of whole-reef biodiversity than do present-day reefs.

**Climate Change: Increasing Storm Activity, Figure 3** A schematic representation of the Intermediate Disturbance Hypothesis. See text for details.

In summary, even through the use of a simple model (the IDH), it becomes clear that the influence of increasing storm activity on coral reef systems is likely to be complex and dependent on many factors, including history (e.g., past disturbance regimes; see *Historical Ecology of Coral Reefs*), plant and animal biology and biomechanics, dispersal to other reefs, growth plasticity (responsiveness to the environment), and, if changes are sufficiently gradual, adaptation (generational shifts in characteristics that improve survival; see *Adaptation*).

## COCOS (KEELING) ISLANDS

---

Colin D. Woodroffe  
 University of Wollongong, Wollongong, NSW, Australia

### Definition

The Cocos (Keeling) Islands are a remote group of islands, forming a single horseshoe-shaped atoll and an isolated island, North Keeling, in the eastern Indian Ocean. They represent the only atoll that Charles Darwin visited and became central to his theory of coral reef development, and have played a central role in several subsequent debates about reef development in relation to sea level.

### Introduction

The Cocos (Keeling) Islands are an Australian Territory in the eastern Indian Ocean, and comprise an atoll that has had a particularly significant place in the development of coral reef studies. This was the only coral atoll that Charles Darwin visited during the voyage of the *Beagle*, and it therefore played a particularly central role in his theory of reef development. It was subsequently visited by several other naturalists. The horseshoe-shaped atoll has a series of sandy reef islands around its rim and a central lagoon that is relatively well flushed during southeast tradewinds, but incompletely flushed during times when winds blow from the northwest.

### History

The Cocos (Keeling) Islands were probably first sighted by Captain William Keeling in 1609. Captain James Clunies Ross visited the islands in 1825 and cleared some vegetation for a settlement. Clunies Ross worked for Alexander Hare who settled on the islands in 1826 with a small entourage of workers, and Clunies Ross himself returned in 1827 and commenced an alternative settlement. Relations between Clunies Ross and Hare deteriorated until Hare left the islands in 1831, after which Clunies Ross' family, known as "Kings of the Cocos," ran the islands as a coconut plantation. In 1955, they became a territory of Australia, and in 1978 the Australian government purchased all the land, except Oceania House, Clunies Ross' residence, and the surrounding grounds.

The atoll became particularly associated with coral reefs because it was visited from 1 to 12 April 1836 by Charles Darwin aboard *HMS Beagle*. During the voyage across the Pacific, Darwin had deduced his remarkable "subsidence" theory of coral reef development in which he considered that a mid-ocean volcanic island would first be encircled by a fringing reef, but that through gradual subsidence of the volcanic basement and vertical growth of the surrounding reef, this would progress through a barrier reef stage, ultimately becoming an atoll. Darwin made a number of insightful observations on the Cocos (Keeling) Islands, but he was particularly pleased because he felt that shoreline erosion and undercutting of coconut trees on West Island supported his theory that the atoll was slowly subsiding. Cocos featured prominently in Darwin's book on coral reefs (Darwin, 1842).

The Cocos (Keeling) Islands were subsequently visited by several other naturalists, in some cases advocating support for alternative theories (Woodroffe and Berry, 1994). Particularly, detailed observations of the reef islands and an estimate of the sediment budget were made by Henry Brougham Guppy during 1888 (Guppy, 1889). Guppy's visit was funded by John Murray and several of his observations consequently supported an alternative view advocated by Murray that atolls built out horizontally through progradation of the reef front. A descriptive account of the islands appeared in a book entitled *Coral and atolls* by Wood-Jones, who spent a year there as the medical doctor during 1905–1906 (Wood-Jones, 1912). Extensive collections of the fauna and an analysis of the historical significance of Clunies Ross' writings were undertaken by Gibson-Hill (1953) and an account of Darwin's time on the atoll was compiled by Armstrong (1991).

### Atoll morphology and physical characteristics

The Cocos (Keeling) Islands comprise a southern horseshoe-shaped atoll (South Keeling Islands, hereafter referred to as Cocos) with more than 20 sandy reef islands around a shallow lagoon (Figure 1), and a northern reef island with a small remnant lagoonlet, North Keeling. These rise from an ocean floor that is about 5,000-m deep, and are the only seamounts within the discontinuous Vening Meinesz chain to reach sea level, making Cocos one of the more isolated atolls.

Cocos is dominated by the southeast trade winds and has persistent swell from the southeast for most of the year, refracting around the atoll but breaking on the entire perimeter. Tidal range is 1.1 m at springs, and the atoll is influenced by occasional tropical cyclones, although there is little evidence of severe storms on the reef flat which does not have large reef blocks or shingle ridges typical of more storm-prone atolls in the Pacific. During short periods, particularly in El Niño years when there are only light winds from the northwest, lagoonal flushing is reduced and episodes of fish kill and coral death have been recorded.

**Cocos (Keeling) Islands, Figure 1** A SPOT satellite image of the main atoll of the Cocos (Keeling) Islands, showing the horseshoe-shaped rim on which the reef islands occur. The lagoon is 8–14-m deep in the north, but contains a reticulate pattern of reefs and numerous blueholes in its southern part, with incursion of sand carried across the reef flat and deposited as sand aprons at the lagoonward terminus of interisland passages. The dark, purplish blue areas in the lee of the two elongate islands (West Island and South Island) are seagrass-covered sand flats (Image sourced from the Cocos (Keeling) Islands Geographical Information System, Geoscience Australia).

### Atoll rim and Lagoon

The horseshoe-shaped rim of the atoll is near continuous except in the northern part where there are openings 12–14-m deep, on the western and eastern side of Horsburgh Island. Drilling and radiocarbon dating indicate that the Holocene rim has accumulated over the Last Interglacial reef limestone encountered at depths of 10–14 m below sea level (Woodroffe et al., 1994) (Figure 2). This older limestone, which represents the rim of an atoll that formed the last time the sea was at or close to its present level, is extremely porous and it plays a significant role in the groundwater hydrology of the atoll (Woodroffe and Falkland, 1997).

The lagoon covers about 190 km<sup>2</sup> and comprises a number of distinct areas. There are shallow sand flats that occur in the lee of South Island, which dry at lowest tides, and support a cover of seagrass. Much of the southern part of the lagoon comprises a reticulate pattern of reefs, some of which are 0–3-m deep, others which are exposed at the lowest tide. This network of reefs separates deeper holes, termed blueholes. These reach 20 m or more deep and have a sporadic cover of branching or foliose corals, much of which is dead. They harbor sharks in their murky waters. The northern lagoon is 8–12-m deep and floored largely with sandy sediments.

The lagoon is incompletely flushed because the inter-island passages are shallow and many dry at low tide (Figure 3a), limiting their effectiveness for the exchange of water from the ocean (Kench, 1998; Kench and McLean, 2004). Sediment is carried into the lagoon and there are sand sheets that are gradually infilling the southernmost blueholes (Smithers et al., 1993). Minor lagoonlets, termed teloks (Figure 3b), occur on the lagoon side of the larger elongate islands. These are very shallow and muddy areas separated from the ocean by a ridge.

**Cocos (Keeling) Islands, Figure 2** Schematic cross-section of the atoll (based on drilling results in Woodroffe et al., 1994). The depth at which the underlying Pleistocene limestone is encountered varies from 8 to 14 m, and reef islands are up to 800-m wide.

**Cocos (Keeling) Islands, Figure 3** Aerial oblique views of the rim of Cocos: (a) Pulu Pandan and the passage to the south of it, on the eastern rim of the atoll; (b) West Island showing the telok (lagoonlet); (c) one of the smaller islands on the eastern rim of the atoll; (d) South Island (Photos C. Woodroffe).

There are minor ridges developed on the lagoon shore, and the teloks experience restricted exchange of water with the lagoon. A similar sequence of ridges, resembling a crab claw, extend on either side of the southern passage, and the distinct succession of ridges that extend from the southeastern shore of West Island appears to be gradually decreasing water movement over the intertidal flats in their lee.

There are extensive areas of the atoll rim and of the lagoon flats that are intertidal and which shoal, or dry, at the lowest tides (Figure 3c). These have provided an environment in which large colonies of *Porites*, including both a massive species and a branching species, have grown upward to a point at which their upward growth is constrained by exposure during the lowest tides. This microatoll growth form was first described from Cocos by Guppy, and has become a focus for research, because the upper surface provides a low-resolution record of past water level. Extensive survey of these corals around the margin of Cocos has shown the subtle variations that exist in the elevation at which this upper limit to coral growth occurs (Smithers and Woodroffe, 2000). The upper surface morphology across two of the larger specimens has enabled an insight into water-level changes relative to this atoll over the past century, indicating minor oscillations in the limit of coral growth and a slight rise in water level that is generally less than that inferred from tide gauges from around the world (Smithers and Woodroffe, 2001).

### Reef islands

Figure 1 shows a SPOT satellite image of the horseshoe-shaped atoll and the islands on its rim (Figures 4a and 4b).

There are two major elongate islands, West Island and South Island which occupy about 60% of the southern rim of the main atoll (Figure 3d). The remainder are small crescent-shaped islands, separated by inter-island passages, most of which shoal at low tide. Horsburgh Island on a lone reef at the north of the atoll, is shaped by wave refraction and reaches elevations of 3–4 m. The majority of islands are perched on a conglomerate platform. Guppy (1889) suggested that this represented a former reef flat, a view supported by Woodroffe et al. (1990). Conglomerate platform (termed brecciated coral-rock by Darwin (Figure 4c), reef conglomerate by Guppy and breccia platform by Wood-Jones) generally reaches up to 0.5 m above MSL, although locally reaching 1 m, and is inundated by waves at the highest tides.

Radiocarbon dating of fossil corals from within the conglomerate indicates that it was formed 4,000–3,000 years BP (Woodroffe et al., 1994). Locally, several corals in their growth position have been identified growing at an elevation above that to which they are presently able to grow. Several of these corals are massive *Porites* that adopted a microatoll form, whereas others are branching *Porites*. These corals provide evidence that the former reef flat was formed around 3,000 years ago when the sea was 50–80 cm higher than it is now with respect to Cocos (Woodroffe et al., 1990).

Darwin drew a schematic cross-section of “Keeling atoll” (although Darwin’s notes indicate that the cross-section was not actually of Cocos, but of Whitsunday Atoll) showing the prominent algal rim (at the reef crest), a near horizontal reef flat, the conglomerate platform (which he termed ledge of coral rock) (Figure 4c), and

**Cocos (Keeling) Islands, Figure 4** Characteristic shorelines of Cocos: (a) Trannies beach at the northern end of West island; (b) a broad reef flat on the eastern rim; (c) extensive conglomerate on the southwestern end of Horsburgh Island; (d) beachrock at the southern end of West Island (Photos C. Woodroffe).

the seaward ridge of the island, steeper on the oceanward side and sloping gradually toward the lagoon. Figure 2 shows a typical section of the eastern rim of the atoll. Many of the islands show the typical cross-sectional morphology that was sketched by Darwin, comprising an oceanward ridge crest, a lower-lying central area, and a less prominent lagoonward ridge. Islands are predominantly sandy, although with shingle in some places, and coral boulders along the oceanward shore of those on the eastern rim where the reef flat is narrowest. There are a number of outcrops of beachrock, bedded dipping parallel to the modern beach, along several of the oceanward beaches (Figure 4d), and occasional outcrops of cay sandstone, which is horizontally bedded and less well lithified.

Darwin inferred different formative processes for islands on windward and leeward sides of the atoll. On the windward (eastern) side he considered that islands accreted solely by addition of material on the oceanward shores, whereas on the leeward (western) side he envisaged that island growth resulted from a combination of oceanward accretion, augmented by lagoonward addition of sediment by waves from the lagoon. By this mechanism, Darwin accounted for the wider islands on the leeward of the atoll. Radiocarbon dating has provided some support for this pattern of accretion on West Island which seems to have accumulated primarily by oceanward accretion, but also with some lagoonward growth (Woodroffe et al., 1999). The crescent-shaped islands on the eastern margin of Cocos were described in detail by Guppy (1889) who proposed a model for their growth involving

spit elongation driven by unidirectional currents through the inter-island channels. This evolutionary model has not been fully tested by dating.

Islands are highest along their oceanward side. The oceanward beach ridge is generally 3–4 m above MSL; however, in some places the fine sand is winnowed from the beach by wind and the beach ridge is topped by a dune. Such dunes are not typical of atoll reef islands in general. South Island has a dune ridge 6–7-m high, reaching as high as 11 m on the southwestern corner of South Island. West Island, which remains the administrative center, has an oceanward ridge that is characteristically 3–4 m above MSL (much of the southern part of this island has been altered during runway construction), but rises to 7 m above sea level in the area where residential buildings have been constructed on a dune. On Home island, where the Cocos Malay kampong is found, the oceanward ridge generally reaches an elevation of 3 m above MSL, but at one location a dune rises up to 5 m (Woodroffe and McLean, 1994).

## Summary

The Cocos (Keeling) Islands consist of the main atoll of Cocos, and the isolated North Keeling (Pulu Keeling) which is Australia's smallest Commonwealth National Park. These rise from deep water, and the southern atoll consists of a near continuous rim with linear islands on the southern margin and a series of crescentic islands on the eastern side. The islands are anchored in their present

location by an underlying conglomerate platform that was formed as a reef flat in mid Holocene when the sea level was higher than present. The islands themselves are largely sand, with restricted dune development on the most exposed oceanward shore. Their elevation is generally 3–4 m above modern sea level, and as the latest tide gauge, installed in 1992, shows evidence of sea-level rise, signs of inundation in the lowest-lying areas may be an omen of more frequent flooding in future (Woodroffe, 2008).

## COLD-WATER CORAL REEFS

André Freiwald  
 Senckenberg Meeresgeologie, Wilhelmshaven, Germany

## Synonyms

Deep-water coral reefs

## Definition

*Cold-water coral reef*. Qualitative term depicting the general contrast to warm-water coral reefs in the tropics and subtropics. The ambient seawater temperature range of known cold-water reefs is 4–14°C. The primary framework is constructed by colonial, azooxanthellate Scleractinia.

*Deep-water coral reef*. Qualitative term describing the general bathymetric setting of these reef systems, which is deeper than 40 m water depth but with the majority thriving in 200–1500 m depth.

## Introduction

Since Linnean times in the eighteenth century, it is known that azooxanthellate corals form substantial aggregations in cold and deep waters and in geographic regions far beyond the shallow-water coral reef belt of the lower latitudes. Until the 1970s, research and sampling of corals in deep waters was restricted to single beam echo soundings and dredge hauls. First visual documentations of this type of ecosystem came from drop cameras and few manned submersible operations, which shed more light in some cold-water reef environments (Squires, 1963; Wilson, 1979). The development of advanced hydro-acoustic sounding systems, such as swath bathymetry and the wider assessment of remotely operated vehicles (ROVs), initiated a worldwide burst to study cold-water coral ecosystems all over the world supported by multinational strategic research programs, which attracted biologists, geologists, and oceanographers to better understand the environmental controls and functionality of this cosmopolitan type of coral ecosystem. Of the 711 known azooxanthellate scleractinian species, 622 live in water depths deeper than 50 m, but only a small group of 6 species is capable to construct reefal framework with *Lophelia pertusa* and *Madrepora oculata* as the most

important cosmopolitan representatives (Messing et al., 2008; Roberts et al., 2009a).

### Dimensions and time constraints of cold-water coral reefs

Cold-water coral reefs are self-sustained and spatially well-defined coral framework-sediment systems measuring tens of meters to kilometers in lateral extension and up to 40 m in thickness, thus influencing local current regimes (Dorschel et al., 2007; Mienis et al., 2007). Most cold-water coral reefs occur in water depths of 200–1500 m, where light is almost reduced or absent, although some reefs exist in much shallower depths due to specific hydrographic conditions, that is, in some upwelling fjord settings (Freiwald et al., 2004; Försterra et al., 2005; Roberts et al., 2006). Reefs generally occur in groups of hundreds if not thousands in a given area like on many places of the Norwegian continental shelf, or off Apulia, Ionian Sea (Fosså et al., 2005; Savini and Corselli, 2010). A focus on the Norwegian coral systems may underpin the substantial reef-constructing capability of these unexpectedly large coral build-up seabed structures. The last glacial ice shields vanished from the shelf about 13–12 ka ago, and the first appearance of *Lophelia* corals was dated 11 ka, short after the last major cold spell, the Younger Dryas Event, from one of the northernmost coral reef provinces in northern Norway (Lopez Correa, unpublished data). This coral age and the high latitudinal position coincides with the onset of the modern oceanographic regime in the north eastern Atlantic, the full establishment of the poleward flowing Atlantic Current system, which seemingly had carried coral larvae as North as to the Stjernsund, Finnmark District. This allows the following assumption. All the cold-water reefs in Norwegian shelf and fjord settings formed within the past 11 ka. This is a relatively short time span to develop mature biogenic seabed structures with the dimensions given above. Performing a first conservative calculation of the  $\text{CaCO}_3$  flux and production rates for cold-water corals, Lindberg and Mienert (2005) concluded that Norwegian corals contribute with flux and production rates reaching 4–12% of that of warm-water reefs. Further south, post-glacial onset of cold-water coral growth in the Porcupine Seabight and southeast Rockall Bank recolonized fossil cold-water carbonate mounds at and after 11 ka, contemporaneously with the onset of the Norwegian coral spread towards the North (Frank et al., 2009). Even further south, cold-water corals fade off just after the Younger Dryas period in the Gulf of Cádiz (Wienberg et al., 2009). The least we can conclude from these data of rise and decline ages is that reef-constructing *Lophelia* and *Madrepora* quickly responds to changing climates and productivity regimes along the northeastern Atlantic continental margin.

### Colony, thicket, coppice, reef

Another apparent character is the low diversity of the primary coral framework constructing species. In contrast to warm-water coral reef framework, only one to three

colonial scleractinian species form the backbone of cold-water reefal framework in a given area (Stanley and Cairns, 1988), thus acting as typical ecosystem engineers. Most significant framework-forming azooxanthellate scleractinians are *L. pertusa*, *M. oculata*, *Solenosmilia variabilis*, *Goniocorella dumosa*, *Enallopsammia profunda*, and *Oculina varicosa*. The latter species lives with endosymbiotic zooxanthellae in the photic zone but without photo-endosymbionts in aphotic depths (Reed, 2002).

The initiation of what will become a reef eventually with time starts with a dense larval spatfall of one or two of the above-mentioned species within a relatively localized area. After metamorphosis of the settled larvae, the corals develop colonies that steadily intermingle with neighboring colonies with time, thus increasingly monopolizing the seabed to form low-relief *thickets* of 10–30 cm height (Squires, 1964). Such thickets provide support and shelter for other organisms that become attracted to the newly created habitat. The corals protect themselves efficiently against competitors with their anti-fouling ability – the skeleton-overcoating tissue or coenosarc. The tissue spread upon those organisms that try to settle onto the coral skeleton, which subsequently becomes encalcified by tissue-controlled precipitation of faint aragonite layers to entomb the epizoids (Harmelin, 1990; Freiwald and Wilson, 1998). With continuing growth of coral colonies within a thicket, a separation of live from dead and tissue-barren framework induces a further important step in the evolution of a complex ecosystem, which is called the *coppice* stage. The tissue-barren framework is now prone to colonization by other sessile organisms, such as foraminifers, hydrozoans, octocorals, serpulids, molluscs, bryozoans, brachiopods, and a diverse array of sponges among others. Therefore, species richness of the coral-associated assemblage of sessile organisms is more diverse in the tissue-barren part of a coral colony than in the upper live part of the colony resulting in a clear faunal zonation pattern (Freiwald, 2002; Mortensen and Fosså, 2006). Of some importance is the infestation of the tissue-barren coral framework by boring and endolithic organisms, which opens a new dimension in micro-habitat colonization but also tend to weaken the framework stability through bioerosion. Most effective bioeroders are boring alecionid, clionaid, and phloeodictyid sponges, which deeply excavate the coral skeleton, thus facilitating the collapse of a colony or even larger parts of thickets (e.g., Beuck and Freiwald, 2005; Beuck et al., 2007, 2010). In the coppice stage, accumulation of coral fragments and remains of the associated skeletal fauna becomes prominent. However, another pre-requisition is needed to transform coppices into a high-relief reef stage – continuous trapping and baffling of suspended particles advected by the bottom-near current regimes. These imported particles entirely consist of the remains of pelagic organisms, such as planktonic foraminifers, coccolithophorids, and pteropods, or they represent a mixture of pelagic and terrigenous silt and clay particles, which are then called hemipelagic sediments. In any case, the matrix infill

between the dead coral framework, either pelagic or hemipelagic, largely contributes to the relief-forming growth of a given reef structure. Without this additive, pure coral framework would disintegrate by processes like bioerosion (see above) and would end as a low-relief coral rubble substrate. Sediment trapping is facilitated by the current velocity decelerating effect of the coral framework, by the mucus binding of particles, and is probably enhanced by large quantities of arborescent agglutinated benthic foraminifers, which live attached to coral skeletons, thus enhancing the baffling capacities considerably (Messing et al., 2008). Particle flux in cold-water coral settings shows a pronounced seasonality as a matter of pelagic production cycles in the fertile surface waters (Duineveld et al., 2007). In general, the current regime at depths of the corals keeps sedimentary particles in suspension and therefore, off-reef sedimentation rates are low if any. The intermingling of biological with geological processes, such as new colonization, coral growth, with subsequent trapping and deposition of suspended fine-grained particles within the loci of coral reefs, is regarded as the main driver to enhance the formation of elevated reef structures within fairly short time scales (Roberts et al., 2006, 2009a and see above).

### Coral habitats, some key species and trophic webs

Mature reefs provide a variety of macro- and microscale habitats, which enhance biodiversity compared to adjacent off-reef habitats. According to Mortensen and Fosså (2006), macro-habitats in a typical reef consist of the *live coral zone* on top and upper flanks, then the *dead coral zone*, which consists of older in situ or fragmented coral framework underneath, and at the base, a belt of *coral rubble zone* mixed with background sediments that surround the structure. Micro-habitats are the surfaces of tissue covered living corals, the detritus laden surface of dead corals, the cavities inside dead coral skeleton, and the free space between coral branches. The live coral zone shows only few characteristic species that cope with the protective and reactive coenosarc of the corals. The eunicid polychaete *Eunice norvegica* is regarded as a non-obligate mutualist that takes food from the corals, cleans the polyps from sediment particles, and stimulates precipitation of coral skeleton to build a protective tube inhabited by the worm (Mortensen, 2001). Moreover, *E. norvegica* is able to actively aggregate pieces of small coral colonies, thus enhancing coral patch formation (Roberts, 2005). Another polychaete frequently observed on living corals is the polynoid *Harmothoe oculinarum* (Jensen and Frederiksen, 1992). The rosalinid foraminifer *Hyrrokin sarcophaga* is known as a common parasite of cold-water corals and associated fauna, such as the file clam *Acesta excavata* (Cedhagen, 1994; Freiwald and Schönfeld, 1996; Beuck et al., 2008). Predatory gastropods in the living coral zone, probably grazing coral tissue and mucus are several coralliophilinid species such as *Babelomurex sentix* and *Coralliophila richardi* (Taviani et al., 2009).

Other characteristic grazers commonly observed in the living coral zone are starfishes like *Porania pulvillus* (Wienberg et al., 2008). Sponges strongly associated with live corals are *Hexadella detritifera*, *Lissodendoryx diversichela*, *Hymenaphia verticillata*, and *Mycale lingua* (e.g., van Soest et al., 2005, 2007). None of the species mentioned above is obligate to cold-water corals, but seemingly they occur in greater abundances in this habitat. The dead coral zone shows highest diversity of coral associates (Mortensen and Fosså, 2006), which use the complex coral framework in various ways but mostly as hard substrate. Only focusing on bivalves here, some characteristic species are *A. excavata*, *Asperarca nodulosa*, *Bathyarca pectunculoides*, *Chlamys sulcata*, and *Delectopecten vitreus*, among many others. Moreover, the coral skeleton is utilized by a vast array of boring organisms; the ones which have an endolithic lifestyle among them are fungi, sponges, polychaetes, and bryozoans (see Beuck and Freiwald, 2005; Beuck et al., 2007, 2010; Wisshak et al., 2005).

Along with increasing research efforts on cold-water coral reef systems, it became increasingly clear that especially the framework-building *L. pertusa* acts as an ecological engineer by providing a variety of habitats, shelter, substrates, and by provision of particulate and dissolved organic matter, thereby attracting a myriad of species (Roberts et al., 2009a; Wild et al., 2008). Regional species filing useful for estimations of gamma diversity found with *Lophelia* started with 895 species (see the seminal review of Rogers, 1999), and later on with 1,300 coral-associates. A current database for the HERMIONE Project of the European Commission listed nearly 2,900 species sorted out for synonyms and calibrated taxonomy using the World Register of Marine Species database ([www.marinespecies.org](http://www.marinespecies.org); Freiwald, in preparation) of which 140 species were described new to science from this reef system during the past 15 years. The most diverse taxa are crustaceans (493 species), mollusks (420 species), sponges (386 species), cnidarians (338 species), and fishes including sharks and rays (278 species). It should be noted that many taxa are yet not sufficiently treated and validated by experts, and that even in well-studied coral sites sampling efforts are yet under-representative to provide a solid base for quantitative biodiversity studies to better understand the entire community and their ecological functioning. Most advanced biodiversity studies from cold-water reefs were provided by Jonsson et al. (2004) from the Swedish Kosterfjord, from Mortensen and Fosså (2006) comparing several reefs from within and off the Norwegian Trondheimsfjord, and from Roberts et al. (2009b) with a study on the Scottish Mingulay reef system.

Unlike warm-water reefs, which also rely on solar radiation as intimate energy resource, cold-water coral reefs are largely dependent on the export of organic matter from primary production in photic surface waters to the seafloor (Duineveld et al., 2007; Davies et al., 2009). In a first comprehensive study of the trophic food web and food supply

from coral habitats along the southeastern Rockall Bank slope, Duineveld et al. (2007) noted a remarkable paucity of deposit-feeders compared to abyssal communities and a short trophic length of the food chain dominated by filter-feeders, added by predators and scavengers. The major food source is from suspended particles. However, our present knowledge is limited if not contradictory as to what extent zooplankton forms a significant part of the suspended load (see Duineveld et al., 2007 for discussion).

## Summary

In the recent years, knowledge on the general distribution, biology, geology, and hydrography has generated a wealth of information on the subject of cold-water coral reefs and their associated communities through the application of state-of-the-art marine instrumentation (Roberts et al., 2009a). Cold-water coral reefs are formed by a small group of colonial azooxanthellate scleractinians as biological engineers and thereby providing a great variety of habitats attractive for a diverse associated community. These framework-constructing corals trap suspended sedimentary particles to generate a three-dimensional structure within an astonishingly short time and at rates comparable to some tropical shallow-water coral reef systems.

## CONGLOMERATES

Lucien F. Montaggioni  
 University of Provence, Marseille Cedex 3, France

## Synonyms

Conglomerate pavements; Conglomerate platforms; Conglomerate promenades; Exposed limestone coral; Rampart-rocks; Shingle conglomerate

## Definition

Conglomerates are defined as exposed, cemented reef-derived detritus, dominantly composed of coral rubble.

*Environment:* mostly, windward sides of reefs; occasionally, on leeward sides near passes and channels.

*Morphology and structure:* Conglomerates exhibit either a planar, mainly horizontal surface (“platform”) or steeply dipping ( $>20^\circ$ ) beds to lee (“basett edge”). Each platform usually has a fairly constant elevation relative to the present mean sea level. But the heights can vary between 0.6 and 1.0 m in areas subject to microtidal regimes and about 1.0–3.5 m in areas subject to macrotidal conditions. Their internal structure reveals the superimposition of distinct beds varying in thickness and grain size, thus reflecting changes in sediment supply and water energy. Locally, there are large coral boulders embedded in the rubble.

*Lithology and diagenesis:* The conglomerate matrices are poorly sorted grainstones, packstones and rudstones. Diagenetic features include typical marine cements (e.g., irregular or isopachous rims of fibrous aragonite, high-magnesian calcite, peloidal micrite) locally showing geotrophic (pendant) habits.

*Origin:* Conglomerates are interpreted as generated by storms and cyclones. These are probably the counterparts of shingle and gravel sheets and ramparts today, accumulated close to sea level. Accordingly, the horizontal surface is generally believed to be primary in origin.

*Age of deposition:* radiocarbon dating of coral and molluscan fragments suggests that deposition occurred between less than 1,000 and about 6,000 years BP in the Pacific.

*Potential use:* indicators of mid-late Holocene sea-level changes.

## CONSERVATION AND MARINE PROTECTION AREAS

---

Jon C. Day  
 Great Barrier Reef Marine Park Authority (GBRMPA),  
 Townsville, QLD, Australia

## Definitions

Conservation is an ethic of resource use, allocation, and protection, with a primary focus upon maintaining the health and biological diversity of the natural world.

Cumulative impacts are the change in the environment which results from the incremental impact of two or more individual events which, when added to other closely related past, present, and reasonably foreseeable probable future events, will compound, magnify, or increase each other or their own environmental impacts.

Ecosystem-based management is an integrated approach to management that considers the entire ecosystem, integrating the ecological, social, economic, and institutional perspectives, and emphasizing the protection of ecosystem structure, functioning, and key processes.

Marine management is a continuous, interactive, adaptive, and participatory management process, comprising a set of related tasks, which collectively work towards achieving a desired set of goals and objectives.

Marine protected area (MPA) network is an organized and systematic collection of individual MPAs, connected in some way by ecological or other processes.

Protected area is a clearly defined geographical space, recognized, dedicated, and managed through legal or other effective means to achieve the long-term conservation of nature with associated ecosystem services and cultural values (Dudley, 2008). Hence, an MPA is a protected area within the marine (intertidal or sub-tidal) realm.

## Introduction

In many parts of the world, coral reefs have been actively conserved for centuries to ensure continuing access to food sources such as fish and shellfish. In most western countries, however, the need to protect coral reefs, and the importance of conserving marine areas, has only been recognized in the last 50–70 years.

Problems arise when marine and coastal resources, such as coral reefs or their resident species, are considered as “open to everyone” with “free” access to virtually all users. Often referred to as “The Tragedy of the Commons” (Hardin, 1968), this commonly leads to excessive use and habitat degradation. These generalizations, of course, vary between countries according to cultural perceptions of private, public, and common property.

The long-held belief that marine resources were almost unlimited and inexhaustible has now proven to be a myth; many living marine resources may be renewable if harvested sustainably, but there are finite limits to marine exploitation. Today, as never before, there are many more pressures on marine environments and a growing awareness of the *cumulative impacts* of those pressures. There are many striking examples around the world of the consequences of poorly managed coral reefs or untimely responses to warning signs.

*Marine protected areas* (often abridged to the term MPAs) are one of a variety of practices at the international, regional, national, and local level to protect coral reefs. Other conservation strategies are being applied at a range of scales from international agreements to local community-based management areas.

Globally, the rate of coral reef degradation, however, greatly exceeds the rate of effective coral reef conservation; hence, far more needs to be done to effectively protect coral reef systems – arguably the most biologically diverse ecosystems on the planet.

## Status of coral reefs globally

Pressures on coral reef systems can be regarded as either human-induced (e.g., mining/quarrying, unsustainable fishing, pollution, heavy-metal impacts, climate change, technological innovations enabling greater use) or natural events (e.g., cyclones, tsunamis). The effects of such pressures on coral reefs can range from negligible to catastrophic, and can be episodic or chronic. It is also important to recognize issues such as *cumulative impacts* (both direct and indirect) and the synergistic effects of such pressures, none of which is easily considered. The combined chronic effects of over-fishing, by-catch, habitat

degradation, pollution, and food-web changes have had significant impacts, resulting in formerly abundant species now being rare and marked changes in resource utilization.

The 2008 Status Report of the World's Coral Reefs (Wilkinson, 2008) estimates that 19% of the world's original reefs are effectively lost forever; 15% are seriously threatened with loss likely in next 10–20 years; and 20% are under threat of loss in 20–40 years. The latter two estimates are made without considering the looming threats of global climate change or that effective future marine management may conserve more coral reefs. If current pressures continue, some consider that 60% of the world's coral reefs may be severely damaged by 2050.

### Key threats to marine conservation and especially coral reefs

1. *Climate change* – Climate change impacts on coral reefs and marine ecosystems are already having marked environmental effects, and the consequent impacts are likely to flow onto the industries that depend on these areas as well as coastal communities. The impacts of climate change on marine biodiversity are being observed throughout the world – carbon dioxide concentrations have increased dramatically in recent decades; the oceans are warming and becoming more acidic, frequently bleaching large areas of coral; and sea-level rise is now flooding some coastal communities.

2. *Land-based water quality* – Coral reefs can be impacted by a variety of land-based pressures including agricultural runoff, inadequate sewage and stormwater treatment, siltation from coastal development, deforestation or beach re-nourishment projects, contamination from petroleum products, etc.

Agricultural runoff can contain herbicides, pesticides, and nutrient fertilizers. Elevated levels of nitrogen and phosphorus may result in algal blooms that can potentially grow much faster and out – compete corals.

Human sewage, often untreated, can add nutrients, microorganisms, and other pollutants to coral reefs and can cause eutrophication.

3. *Unsustainable harvesting (fishing or collecting)* – Unsustainable harvesting can cause a variety of negative impacts on coral reefs, including altering trophic interactions causing indirect environmental effects. For example, where predators have largely been removed, increases in the population of their prey have resulted in unexpected flow-on effects. Unsustainable fishing or the depletion of fish spawning sites can also reduce genetic variation in a population, making it harder for species to adapt to environmental change.

Over-fishing can have major impacts on target species and has led to the extinction of species in some areas (e.g., Queen Conch), but can also have major impacts on non-target species (by-catch) as well as cause habitat destruction.

Discarded fishing gear (e.g., ghost nets) can damage reefs and also have major impacts on marine biodiversity. Marine debris, especially plastics and monofilament fishing line, can abrade corals and prove lethal for birds, fish, and turtles that become entangled in it or mistake it for food and ingest it.

4. *Direct physical damage (e.g., blast fishing, dredging, mining, infilling, etc.)* – Many fishing practices harm coral reefs by physically damaging habitat or by killing non-targeted species. Blast fishing occurs in some parts of the world, whereby underwater explosions are used to injure fish so that they float to the surface where they are easily captured. The blast, however, also destroys coral and flattens the reef structure. In some places, fishermen use cyanide or other poisons to stun fish so that they can be captured alive, but small fish and coral polyps may also be killed.

Limestone mining or infilling for coastal developments have obvious major impacts, completely destroying coral reefs or severely altering hydrological flow patterns.

The depletion caused by the harvest of coral and “live rock” for the aquarium/curio trade has damaged many reefs around the world.

5. *Indirect impacts from marine or coastal developments* – Human activities on land such as the building of ports, industrial infrastructure, deforestation, tourism facilities, or other coastal developments can lead to increased rates of sedimentation affecting adjacent reefs. High sediment loads can smother corals or decrease light penetration, thereby reducing the photosynthetic ability of the symbiotic algae in coral.
6. *Unsustainable tourism/recreation* – Anchors, accidental boat groundings, and propeller strike can all crush and scar coral. The fins of divers and snorkelers and even their diving equipment can inadvertently damage coral. Well-meaning tourists may feed reef fish, but this can change feeding behavior with other flow-on effects. Similarly, shell collecting, fossicking, and uncontrolled reef-walking can have detrimental impacts on corals.
7. *Invasive species (pest plants, animals, diseases) or outbreaks of native species* – Invasive marine species may be introduced by a variety of vectors, including ballast water discharge, biofouling on vessel hulls or within internal seawater pipes in commercial and recreational vessels, aquaculture operations (accidentally or intentionally) and aquarium imports, as well as marine debris carried by ocean currents.

At high densities, outbreaks of species that eat juvenile or adult corals can cause major problems for reefs and their associated species (e.g., the crown-of-thorn starfish, a long-spined species of sea urchin, and a small gastropod snail have all caused major problems in many coral reefs around the world).

The types and extent of diseases attacking corals have increased markedly in recent years and coral diseases such as Black Band and White Plague are

becoming more prevalent, especially following bleaching stress. Bacteria in sewage pollution are a suspected cause of White Band disease in corals.

8. *Shipping and related issues* – Oils and hydrocarbons inadvertently discharged, or deliberately washed overboard, can cause impacts, especially if they occur during coral spawning. Coral reefs and mangroves are more susceptible to the impacts of oil spills compared to sandy beaches or seagrass beds. Other ship-sourced threats include sewage discharge and toxic discharges, as well as the impacts of antifouling paint used on vessels.

### Effective reef conservation

An emerging realization is that effective marine conservation requires a lot more than just protecting areas in MPAs alone; in order to provide for the future, including any sustainable use, effective reef conservation requires the following:

1. Understanding, and effective management, of the wider context (i.e., the surrounding waters and the ecological processes that influence the coral reef as well as the nearby catchment areas); this means, in effect, integrated land/sea management;
2. Sustainable resource utilization (especially fishing and collecting) of the coral reef as well as the surrounding marine area;
3. Effective marine protection (which may be by declaring an MPA through a legal or other effective means);
4. Effective stakeholder involvement (industry and community); and
5. Where appropriate, the incorporation of traditional management approaches.

### Marine protected areas

In recent decades, considerable efforts have occurred worldwide to establish MPAs to improve marine conservation. A diverse array of MPA types, each with its own label and priorities, has arisen in coastal and marine areas throughout the world.

In this instance, MPA is used as a broad generic or “umbrella” term, reflecting the IUCN definition amended in 2008 of a protected area:

*A clearly defined geographical space, recognised, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values.*

IUCN has seven categories of protected area, ranging from highly protected “no-take” areas, intended only for scientific research (IUCN Category IA), through no-take areas that may be accessed by the public but where virtually all types of extraction are prohibited (IUCN Category II), to multiple-use areas in which the sustainable extraction or collection of natural resources may occur (IUCN Category VI).

One of the better known MPAs with coral reefs is the Great Barrier Reef Marine Park (GBRMP), covering

344,400 km<sup>2</sup> on Australia’s northeast coast. Because of the iconic status of the Great Barrier Reef, many people believe the entire area is a marine sanctuary or marine reserve, and therefore protected equally throughout. While the entire area is protected by law, many do not understand that the GBRMP is a multiple-use MPA, in which a wide range of activities and uses are allowed, including many extractive industries in certain zones (but not mining nor drilling for oil), while still protecting one of the world’s most diverse ecosystems (refer to the GBRMP Activity Matrix, [Figure 1](#)).

A major rezoning of the GBRMP occurred from 1999 to 2004, with the primary aim to improve the protection of the range of biodiversity throughout the GBRMP. The final outcome included an increase in “no-take” zones to over 33% of the entire area, with an additional 33% zoned to ensure comprehensive habitat protection (refer to map showing the zoning in the GBRMP, [Figure 2](#)).

The comprehensive, multiple-use zoning system in the GBRMP (which comprises IUCN categories IA, II, IV, and VI) is a systematic network that effectively governs all human activities, providing high levels of protection for specific areas, while allowing a variety of other uses, including shipping, dredging, aquaculture, tourism, boating, diving, commercial fishing, and recreational fishing, to occur in certain zones.

The most optimistic estimates indicate that less than 1% of the world’s oceans are currently in any type of MPA, and only a small proportion of coral reefs is adequately protected. While there are many effective MPAs, there are also many ‘paper parks’ that are not achieving what was intended when they were declared.

Recent declarations of several large MPAs, which include coral reefs such as Papahānomoukūakea (NW Hawaiian Islands) and the Phoenix Islands in the Republic of Kiribati, are encouraging, but collectively are still not enough to meet global targets set by international conventions such as the Convention on Biological Diversity.

### The benefits of MPAs

Single MPAs, particularly those containing appropriately chosen “no-take” areas, can provide a range of benefits including helping to maintain biodiversity, enhance nonconsumptive opportunities, and improve stocks that have commercial and recreational value in adjacent areas.

The benefits of MPAs, however, will be greatly increased if they are effectively linked to provide ecologically coherent networks. Any MPA network should be designed to link individual areas and comprehensively represent the region’s spectrum of marine life characteristics, not just a subset of habitats or only species of special interest.

The focus on MPA networks recognizes the fact that a broad-area-integrated network that has been systematically developed and managed is often more effective than a series of small, highly protected areas surrounded by “a sea” of unmanaged activities.

Conservation and Marine Protection Areas, Figure 1 Map showing part of the GBRMP zoning plan.

| <b>GBRMP Zoning</b><br>(see relevant <i>Zoning Plans and Regulations</i> for details) |        | General Use Zone | Habitat Protection Zone | Conservation Park Zone | Buffer Zone | Scientific * Research Zone | Marine National Park Zone | Preservation Zone |
|---------------------------------------------------------------------------------------|--------|------------------|-------------------------|------------------------|-------------|----------------------------|---------------------------|-------------------|
| Aquaculture                                                                           | Permit | Permit           | Permit*                 | ×                      | ×           | ×                          | ×                         | ×                 |
| Bait netting                                                                          | ✓      | ✓                | ✓                       | ×                      | ×           | ×                          | ×                         | ×                 |
| Boating, diving, photography                                                          | ✓      | ✓                | ✓                       | ✓                      | ✓*          | ✓                          | ✓                         | ×                 |
| Crabbing (trapping)                                                                   | ✓      | ✓                | ✓*                      | ×                      | ×           | ×                          | ×                         | ×                 |
| Harvest fishing for aquarium fish, coral and beachworm                                | Permit | Permit           | Permit*                 | ×                      | ×           | ×                          | ×                         | ×                 |
| Harvest fishing for sea cucumber, trochus, tropical rock lobster                      | Permit | Permit           | ×                       | ×                      | ×           | ×                          | ×                         | ×                 |
| Limited collecting                                                                    | ✓*     | ✓*               | ✓*                      | ×                      | ×           | ×                          | ×                         | ×                 |
| Limited spearfishing (snorkel only)                                                   | ✓      | ✓                | ✓*                      | ×                      | ×           | ×                          | ×                         | ×                 |
| Line fishing                                                                          | ✓*     | ✓*               | ✓*                      | ×                      | ×           | ×                          | ×                         | ×                 |
| Netting (other than bait netting)                                                     | ✓      | ✓                | ×                       | ×                      | ×           | ×                          | ×                         | ×                 |
| Research (other than limited impact research)                                         | Permit | Permit           | Permit                  | Permit                 | Permit      | Permit                     | Permit                    | Permit            |
| Shipping (other than in a designated shipping area)                                   | ✓      | Permit           | Permit                  | Permit                 | Permit      | Permit                     | Permit                    | ×                 |
| Tourism programme                                                                     | Permit | Permit           | Permit                  | Permit                 | Permit      | Permit                     | Permit                    | ×                 |
| Traditional use of marine resources                                                   | ✓*     | ✓*               | ✓*                      | ✓*                     | ✓*          | ✓*                         | ✓*                        | ×                 |
| Trawling                                                                              | ✓      | ×                | ×                       | ×                      | ×           | ×                          | ×                         | ×                 |
| Trolling                                                                              | ✓*     | ✓*               | ✓*                      | ✓*                     | ×           | ×                          | ×                         | ×                 |

**PLEASE NOTE:** This guide provides an introduction to Zoning in the Great Barrier Reef Marine Park. Relevant Great Barrier Reef Marine Park Zoning Plans should be consulted for confirmation of use or entry requirements.

\* Additional restrictions / conditions apply.

**ACCESS TO ALL ZONES IS PERMITTED IN AN EMERGENCY.**

Conservation and Marine Protection Areas, Figure 2 GBRMP “activities matrix”.

### Tools for marine management

MPA managers generally do not manage natural systems or specific marine species *per se*; rather they manage the human impacts associated with those resources. Marine management is usually undertaken to achieve a desired set of goals and objectives; it is important that these goals and objectives are clearly established and widely known.

Ecosystem-based management and adaptive management are two key aspects of the effective management of any MPA, and these are particularly important because of the following:

1. The interconnectedness of different habitats of the marine environment and the interdependency upon neighboring biological communities;
2. The impacts from adjacent land or sea areas that may threaten the integrity of even the best managed MPA;
3. The three-dimensional aspects of what needs to be managed (few MPAs are well known, easily viewed, or easily “delineated” for management purposes, which means they are hard to see, hard to manage, and enforce). “Out-of-sight, out-of-mind” is part of the problem;

4. Ownership issues (for most marine areas worldwide, open-access resources are poorly or insufficiently regulated).

When used in the context of the above management and planning approaches, the following management tools are widely used by MPA managers:

*Zoning* – Spatial allocation using zoning is an accepted practice within many MPAs around the world. Zoning can separate conflicting uses and provide for high levels of protection for specific areas while allowing a variety of uses, including fishing, to continue in other zones.

*Permits and licensing* – When used in conjunction with a zoning plan and other management tools, permits, and licences can:

- (a) further regulate use in high-use or sensitive areas;
- (b) encourage responsible behavior in users and assist in monitoring activities; and
- (c) require the collection of data for planning and management.

Certain permit applications may also trigger the need for a comprehensive environmental impact assessment to be undertaken.

*Enforcement and surveillance* – Without an effective compliance and enforcement program, an MPA will not achieve its objectives. In time, its regulations will neither be accepted nor complied with by users or locals. Implementation and enforcement of regulations may include checking locations, size restrictions, bag limits, fishing season, or gear type, and can protect habitats, by-catch species, and spawning stock.

Enforcement and compliance can be very expensive because of the costs of resources, including trained personnel and access to appropriate vessels, aircraft, or specialist equipment. Enforcement should not, however, be considered as the only management approach or the tool of last resort.

*Public education and community engagement* – These are both integral to effective marine management. Communicators must build awareness of the threats and instil an acceptance for change. Effective public education and enlisting the assistance of key stakeholder groups, combined with enforcement and compliance, can result in valuable outcomes.

*Research and monitoring* – Research and monitoring can help MPA managers to diagnose problems, prioritize and implement solutions, assess the results and effectiveness of management actions, and forecast future conditions. Having the best available information for decision making helps ensure effective marine management of an MPA.

The above are only some of the main management tools used in coral reef conservation; other spatial tools include plans of management, specific closures, or special management areas. Non-spatial management tools include effective legislation, advisory committees, industry partnerships, best practice guidelines, or user fees such as

the “Environmental Management Charge” applied in the GBRMP.

### Key lessons learnt

1. In most MPAs worldwide, there are real challenges in maintaining existing levels of marine management, let alone coping with rapidly escalating levels of use or increasingly complex issues, such as climate change. Finding the right balance between protection and sustainable use is essential, and issues like cumulative impacts are becoming increasingly important to address.
2. An integrated management framework is important for effective marine management. Without it, intersectoral conflicts, incompatible activities, and inefficient systems will prevail. Integration across use sectors, levels of government, and the land–sea boundary are all fundamental to effective ocean governance and marine conservation.
3. Manage at the ecosystem level, not for single species. Most fishery management efforts focused on managing a single target species have failed. The more appropriate and effective approach requires managing all components and ecological processes as part of ecosystem-based management.
4. Local communities and indigenous people should be involved in marine management; successful examples of effective conservation have comprised a combination of “top-down” approaches (through government working with appropriate agencies or organizations), combined with effective “bottom-up” input involving community engagement. Widespread public support is essential if marine conservation efforts are to be successful and sustainable.
5. Apply the precautionary principle. We will never know precisely how coral reef ecosystems function or how they will cope with pressures such as climate change. But enough is known to cautiously proceed with management, comprehensively using the best available science and expert opinion (not waiting for perfect information) and adaptively managing as we continually learn.
6. Ensure that all MPA planning is open, transparent, collaborative, and adaptive, using the best available scientific, traditional, and local knowledge. Accommodate the economic, social, and cultural aspirations of communities within the ecological constraints.
7. Better technology can be a “double-edged sword” – while it may assist management (e.g., remote sensing, satellite imagery), it can also mean that users are able to access areas and resources that previously were inaccessible.

### What is the future for reef conservation?

As the global population increases markedly, the pressures on coral reefs are increasing significantly as are the difficulties in ensuring reef conservation. Regrettably, many

governments are not focused on long-term reef conservation outcomes, focusing more on short-term development issues or resource use; this means that matters such as long-term sustainability, adequate resourcing for relevant agencies, and funding for conservation are often of lower priority.

The conservation of the world's coral reefs is today at "cross-roads"; paraphrasing Kingsford et al. (2009)

1. In most areas, there is sufficient knowledge to implement effective policy, but effective implementation largely depends upon education, political will, community aspirations, and social and economic capacity;
2. As the knowledge of what is required for coral reef conservation has increased, so have the pressures; and
3. Proactive reef conservation measures that aim to build resilience to better cope with the likely pressures are considerably more cost efficient and are often less risky than waiting until the pressures have occurred and then trying to address them through reactive management.

## COOK, JAMES (1728–1779)

---

James Bowen

Southern Cross University, Lismore, NSW, Australia

James Cook was the first of the great explorers of the eighteenth century to present a comprehensive account of the almost invisible reefs in the great open expanses of the Pacific Ocean. Intensified speculation had been mounting on such hazards to navigation when the destructive power of coral reefs was given sensational publicity in Cook's account of his successful discovery of the mysterious and elusive Great South Land, following the British scientific expedition in command of the *Endeavour* to Tahiti in 1769 for scientists to observe the Transit of Venus.

While subsequently exploring the unknown eastern coast of New Holland, on June 11, 1770, his ship crashed into one of the invisible reefs and the eventual discovery

of a way out of the bewildering complexity of the “labyrinth” of submerged reefs created a sensation. He published his description of the impact and the beaching of the vessel for repairs. Once safe in the ocean, Cook wrote one of the most powerful coral reef images ever: “A Reef such as is here spoke of is scarcely known in Europe, it is a wall of Coral Rock rising all most perpendicular out of the unfathomable Ocean... the large waves of the vast Ocean meeting with so sudden a resistance make a most terrible surf, breaking mountains high.”

In 1770, after his encounter with the Great Barrier Reef, Cook had become aware of a major scientific controversy among European and British naturalists that in some mysterious way coral reefs were built neither by rocks nor by petrified plants as 2,000 years of tradition had supposed, but were the production of microscopically small animals, then part of the extensive range of unknown, unclassified organisms collectively termed “insects”.

Barely 4 years later, during his second 1772–1775 exploratory voyage in the Pacific in command of the *Resolution*, as he navigated past continental islands in the central Pacific with elevated relict fringing reefs, he recorded in his *Journal* for June 1774 his puzzlement “If these Coral rocks were first formed in the Sea by animals, how came they thrown up, to such a height? Has this Island been raised by an Earth quake or has the sea receded from it? Some philosophers [scientists] have attempted to account for the formation of low isles such as are in this Sea, but I do not know of any thing has been said of high Islands or such as I have been speaking of,” thereby providing speculation for further reef research.

## CORAL CAY CLASSIFICATION AND EVOLUTION

Scott G. Smithers, David Hopley  
 James Cook University, QLD, Townsville, Australia

### Definition

A coral cay is an island formed from sediments derived from the reef on which it sits and swept by refracted waves to a focal point on the reef flat where they are deposited. A cay initially may remain intertidal and lack vegetation, but with time it is likely to build up to be above sea level, acquire a vegetation cover, and become partially lithified.

### Introduction

Islands associated with coral reefs have been occupied or used by humans for millennia. They became known to western society as voyages of discovery crossed tropical waters. A distinction has been made between “high” islands composed of continental rocks and “low” islands of biogenic carbonate sediments produced by reef organisms. The variety of morphologies that were observed became a focus of early studies:

“There are different opinions amongst ingenious theorists, concerning the formation of such low islands”.

(James Cook, 17 April, 1777)

Scientific studies of reef islands were first made in the nineteenth century in south-east Asia and the Australian Great Barrier Reef (GBR) and subsequently in the Pacific and Indian Oceans and in the Caribbean Sea (see [Table 1](#); [Stoddart and Steers, 1977](#)) (see [Steers, James Alfred \(1899–1987\)](#); [Stoddart, David Ross \(1937–\)](#)).

As the diversity of form became evident, various attempts at classification were undertaken. More recently research has extended to understand processes that form and maintain coral cays and their origin, age, and evolution. Many of these investigations, especially the development of classifications, were based on studies of the GBR ([Spender, 1930](#); [Steers, 1929, 1938](#); [Fairbridge, 1950](#); [Stoddart and Steers, 1977](#); [Hopley, 1982, 1997](#); [Hopley et al., 2007](#)). The GBR is the largest reef province in the world, which when combined with the adjacent Torres Strait contains over 1,000 islands including approximately 350 coral cays ([Hopley et al., 2007](#)). Stretching over 15° of latitude and with reefs extending from the mainland to the shelf edge, the GBR provides a diversity of environments which are responsible for the great variety of coral cay types found within its waters (see entry: Section 10.1.3 in [Hopley et al., 2007](#)).

### Cay formation: wave influences

Coral cays generally occur on reef flats at or very close to sea level. The reef flat need not be large (many occur on small reefs <1 km<sup>2</sup>), and some sand cays in the Maldives have been shown to develop over lagoonal sediments while the reef flat is still evolving ([Kench et al., 2005](#)). A supply of biogenic sediments is fundamental for cay formation, but most reef tops have partial veneers of sand and shingle and there are many with diffuse sediment sheets that remain unconcentrated. The most critical factor for cay formation is the centripetal pattern of sediment movement produced by waves and currents in response to reef shape; centripetal sediment transport delivers sediment to a focal point or depositional node where it may accumulate (see [Hydrodynamics of Coral Reef Systems](#); [Wave Shoaling and Refraction](#); [Waves and Wave Driven Currents](#)).

Two related features of wave transformation over a reef control whether or not deposition is spatially concentrated. The first is the convergence of waves. The depth of water just beyond the reef front means that waves do not fully

<sup>a</sup>Atoll motus

refract and accommodate themselves to the reef front. Instead, around the reef perimeter except at the windward tip, they pass over the reef crest at a slight angle, leading to a zone of wave convergence toward the leeward reef flat. This is indicated clearly by the pattern of the aligned coral zone (see *Geomorphic Zonation*) on many reefs. However, centripetal transport and concentrated deposition are not developed on all reefs. Reef shape is critical, as it controls the pattern of refraction. Convergence of wave trains is most likely on oval reefs. However, interference of wave patterns by upwind reefs may mean that the waves approaching a reef are already refracted. In these circumstances, a clear focal point from further refraction may not be achieved, impeding island formation.

The second important feature of waves is their ability to transport sediment. Much wave energy is dissipated on the reef edge due to breaking and reflection. However, some energy is transmitted and smaller waves reform beyond the break point and move over the reef, where they are attenuated very slowly, unless water depths are exceptionally shallow or the bottom is very rough. The competency of reformed waves to move sediment is markedly diminished, even during major storms. Thus, coarse sediment is likely to be deposited on the windward margin where a shingle cay may form. Where waves tend to break normal to the reef front, this may be a rampart-like linear

Coral Cay Classification and Evolution, Figure 1 Windward shingle ridge parallel to reef front, Turtle 2 Reef GBR.

feature paralleling the reef crest (Figure 1; see *Shingle Ridges*). Alternatively, there may be sufficient refraction at the apex of a reef to concentrate coarser sediments into a compact island.

Generally, waves propagating over the reef flat beyond the rim are only competent to transport sands and finer sediments. As these waves slowly attenuate, sediments may be transported a considerable distance leeward.

Deposition occurs where refracted waves converge, either along the center of the reef or in a nodal area toward the lee. However, on very large reefs, waves that are distant from the reef front may become incompetent to transport even fine sediments that remain spread over the reef flat. Leeward sand cays thus form where there is both a centripetal convergence of refracted waves and sufficient wave power to transport sediments to a focal point. On large reef flats, sediment transport by refracted waves may be augmented by locally generated short-period wind waves, with their influence growing as rising tides increase fetch over broad reef platforms (Samosorn and Woodroffe, 2008). In high-energy areas and/or on smaller reef platforms, sediments may be swept entirely off the reef. Because maximum wave height over a reef flat is constrained by water depth (which is tidally modulated) and wave attenuation is a function of friction, a reef energy window index can be calculated from the ratio of the reef flat depth at mean spring high tide and reef width, which indicates potential geomorphic activity over a particular reef platform (Kench and Brander, 2006).

### Cay sediments

The textural characteristics of reef sediments play an important role in the bimodal distribution of reef flat sediment deposition observed on many reefs. Because shingle and rubble tend to break down into sands of approximately  $2\phi$  (Orme, 1977), a distinctly bimodal distribution of sediments and depositional environments develops under the wave-energy conditions described above (see *Sediments, Properties; Sediment Dynamics; Reef Flats*). Nonetheless, the basic division of reef islands into windward shingle cays and leeward sand cays is very much oversimplified.

Studies of GBR cays (Maxwell et al., 1961, 1964; McLean and Stoddart, 1978) suggest that for each cay type, either sand or shingle, sediments textures are remarkably uniform. McLean and Stoddart (1978) examined sediments of cays on the northern GBR and found that shingle is relatively homogeneous in composition (mainly *Acropora* clasts) but varies in size and shape, whereas sand cay sediments are mainly well-sorted ( $<1\phi$ ) medium to coarse sands ( $0-1.5\phi$ ) derived from a wider range of biota and are compositionally very similar to reef flat sediments. Where winds blow from one prevailing direction, the beaches on sand cays contain the coarsest sediments, particularly on the windward shore. Winnowing by the wind transports finer sand to the cay interior or berm, though dune structures are rare or poorly developed on most cays. McLean and Stoddart (1978) found that the finest sediments were associated with soils, either as a component of the active soil profile or within buried soil horizons.

The broad patterns established for GBR cay sediments are generally applicable elsewhere. Although sand cay sediments occur within a narrow textural range, small but distinct variations between cays develop due to

differences in proportions of constituent components (which may be related to the nature of the reef flat), differences in distances, modes, and rates of transport from source area to cay (dependent on the size of the reef and the location of the cay upon it), and variations in residence time since deposition. Coral cays may include minor amounts of siliciclastic sediment; pumice fragments floated in from volcanic source areas are common and can form distinctive strata up to 30 cm thick on some cays. Pumice fragments up to 0.5 m in diameter have been found, but more commonly they range between 1 and 5 cm in size. Occasionally, continental rocks reach cays in the roots of floating trees.

### Criteria used in classification

Several coral cay classification schemes have been proposed to accommodate and in some cases explain the variation in morphological and compositional diversity outlined above. Steers (1929) suggested three classes of reef islands based on his detailed work on the GBR in the 1920s and 1930s: sand cays, shingle cays, and low wooded islands. Spender (1930) proposed a general classification of reefs and low islands that recognized five classes of reef, four of which support reef islands (1) a sand cay; (2) a sand cay and unvegetated rampart; (3) a sand cay and vegetated rampart without extensive mangroves across the reef platform; and (4) a sand cay, vegetated rampart, and mangrove-forested reef flat. Spender referred to this latter class as “island reefs” but they are synonymous with Steers’s low wooded islands by which they are better known today (see *Low Wooded Islands*).

Fairbridge (1950) identified five classes of island based on sediment type, vegetation cover, and the occurrence of emergent reef flat – a function generally of late Holocene relative sea-level history that can vary geographically (Hopley et al., 2007). Fairbridge’s cay classes were (1) unvegetated sand cays; (2) vegetated sand cays; (3) shingle cay, with or without vegetation; (4) sand cay with shingle ramparts, vegetated or unvegetated islands and with mangrove swamp over reef top; and (5) island with exposed platform of older emergent reef, sometimes fringed by more recently deposited sediments. Hopley (1982, 1997) reviewed the literature on GBR reef islands and their classification and concluded that four criteria can be used to define a reef-island classification equally applicable to coral cays formed in other reef regions. The four key criteria that form the basis of reef-island classification are as follows:

*Criterion 1: Sediment type.* Sand, shingle, or a mixture of both can dominate reef islands. In areas of moderate energy and a prevailing wind direction, shingle is typically located toward the windward edge of the reef platform, and sand cays generally form near the leeward margin due to hydrodynamic sorting. This distinction may be less clear in areas rarely affected by storms where shingle deposits may be lacking or on reefs affected by frequent high-energy storms where successive ridges

of storm-deposited coarse material may form the island core, but are surrounded by a sandy beach (e.g., Lady Musgrave Island, southern GBR). Reef islands developed where wind direction seasonally reverses are also less likely to show the classic bimodal distribution of sediments, especially on smaller reef platforms where mixing is likely.

*Criterion 2: Island location on the reef platform.* Where sediments are available and the reef platform size and energy regime allow sorting to occur, shingle cays form near the windward reef margin and sand cays to leeward. On some platforms, reef islands may occupy a significant proportion of the reef flat; coral cays on lagoonal reefs within Maldivian atolls can occupy as much as 56% of the reef top (Kench et al., 2008). Where cays are large relative to the reef platforms on which they sit, it is difficult to define whether a cay is windward or leeward, as is also the case where cays are located centrally on the reef due to either seasonal wave climate reversals or a function of reef geometry.

*Criterion 3: Island shape.* Cay shape broadly falls between elongate and compact (oval to round). This trait is largely controlled by the interaction of reef shape and wave refraction and transformation around and across a reef. Compact islands form where sediment transport to a single focal node is most efficient. Therefore, the directional consistency and energy of the prevailing wave climate and the complicating effects of obstructions such as adjacent reefs on the transfer of this energy to the reef platform also influence island shape. Generally, but not always, compact cays are more stable than elongate cays; the ends of which can be particularly sensitive and move with small changes in wind and wave direction with a seasonal periodicity (e.g., Flood, 1986).

*Criterion 4: Vegetation cover.* Coral cays are either unvegetated or vegetated, with the extent of vegetation often reflecting island size, age, and stability. Climate, especially rainfall and frequency of storms, can also be important, but larger, older, and more stable islands generally possess better soils and groundwater aquifers best able to sustain vegetation. Reef-island vegetation is discussed further in Section Reef-island vegetation.

The four criteria above can be used to describe and classify reef islands that range from small and unstable unvegetated sandy cays to complex low wooded islands (see Section Classification: island types). It is important to note that two criteria – vegetation cover and island shape – may change abruptly, especially on reefs exposed to extreme events. For example, Pickersgill Cays on the GBR were reported as slightly vegetated by the Australian Pilot early in the twentieth century but unvegetated when Spender (1930) and Steers (1929) visited in 1929 and were again unvegetated in 1973 (Stoddart et al., 1978a). Rapid changes in reef-island morphology can be established by comparing aerial photographs or accurate GPS surveys at event and seasonal time scales, and these methods

commonly document significant shifts in shoreline at these short time scales (e.g., Frank and Jell, 2006). Historical maps available for some reef islands can be compared with later versions to show significant change over the past 50–100 years (e.g., Stoddart et al., 1978b; Flood, 1986). Relict beach rock outcrops indicate the position and shape of cay shorelines in the longer term past that can be very different to the present day morphology. Cay dynamics are covered in Section Factors influencing cay stability.

### Classification: island types

The main classes of coral cay are described in the following section. The defining features of major reef-island classes are depicted schematically in Figure 2.

#### Unvegetated cays

Unvegetated cays clearly lack vegetation. They are generally small and unstable; both conditions constrain the establishment and survival of plant cover. A mean area of just 0.5 ha was determined for 18 unvegetated cays surveyed in the 1973 northern GBR expedition (Stoddart et al., 1978a). They may be composed of sand and/or shingle and can be either elongate or compact. They are the most common cay type (see *Unvegetated Cays*).

##### *Unvegetated sand cays*

Linear unvegetated sand cays form on medium to large planar reefs (see Chapter *Reef Classification by Hopley, (1982)*) of elongate shape where wave refraction generates opposing wave trains that meet along a central axis and where sediment accumulation takes place. Linear unvegetated cays may also form where winds seasonally reverse, producing an elongate, spit-like accumulation toward the leeward reef margin. Hopley (1982) considered that the migrating linear sand banks on the large planar reefs of Princess Charlotte Bay, northern GBR resulted from seasonal shifts between dominant south-easterly trade winds and lighter, more northerly monsoonal winds. Bidirectional monsoons have also been linked to the abundance of elongate unvegetated cays in Indonesia (Tomascik et al., 1997). Compact unvegetated cays form where strong centripetal sediment transport focuses deposition within a restricted locus (Figure 3a). Many are highly mobile and unstable (Hopley, 1978; Aston, 1995), especially the smaller (<0.1 ha) “ephemeral” cays that may be submerged at high tide (Figure 3a). Stoddart et al. (1982) concluded that many of these cays in the Caribbean, such as Paunch and Curlew Cay, may be second generation features reformed following the destruction of larger cays during storms. Larger unvegetated cays up to 400-m long and 120-m wide are often flanked by beach rock, suggesting greater stability.

##### *Unvegetated shingle cays*

Linear unvegetated shingle cays are very unstable reef islands, vulnerable to reworking and erosion near the reef front (Figures 2b and 3b). They are typically the product of

**Coral Cay Classification and Evolution, Figure 2** Schematic plan views of major reef-island classes: (a) unvegetated sand cay; (b) unvegetated shingle cay; (c) vegetated sand cay; (d) multiple island (with vegetated shingle island); (e) mangrove island (note no spurs and grooves as low-energy setting); (f) low wooded island.

high-energy storms and form as shingle ramparts coalesce. Unvegetated shingle cays can remain reasonably intact between storms, and cementation of basal sediments can occur, forming bassett edges (cemented lower parts of shingle ridges), which steeply dip away from the reef front (see *Bassett Edges*). However, bassett edges preserved after ramparts are eroded occur like outcrops of beach rock on many reef flats, suggesting that unvegetated shingle cays have also limited longevity (Hopley, 1982). Compact unvegetated shingle cays are generally restricted to small reefs, but vary from relatively mobile mounds of shingle and rubble through to complex structures with some degree of cementation.

### Vegetated cays

Eventually some unvegetated cays achieve sufficient stability for vegetation to successfully establish and this vegetation may confer additional stability (see Section Reef-island vegetation). As for unvegetated cays, vegetated cay sediments range from pure sand to shingle, and shapes range from linear to compact (see *Vegetated Cays*).

#### *Vegetated sand cays*

Vegetated cays are usually more stable than unvegetated cays, but can still change morphology and position. For example, in the Caribbean, Hurricane Hattie in 1961 completely removed St. George's East Cay that was 110-m long and 0.3 ha in size (Stoddart et al., 1982). Hopley (1982) argued that compact vegetated cays

(Figures 2c and 3c) are more stable than linear cays because (1) they usually have a proportionally larger vegetated area; (2) beach rock outcrops give better protection as they armor the beaches rather than become detached as on unvegetated cays; and (3) colonizing species tend to dominate linear cays for a longer period. Some vegetated cays are barely emergent at high tide, but others support dunes that rise several meters (Figure 3c). Beach rock can occur on the more stable long-axis flanks of compact and even linear vegetated cays, with massive outcrops exposed by subsequent erosion. For example, beach rock was absent from only one (Upolu Cay) of the 17 vegetated cays on the GBR mapped by Stoddart et al. (1978a). Flood (1977) also noted that beach rock was common on the 14 vegetated cays in the Bunker and Capricorn Groups he examined. Moderate though not necessarily extended stability is required for beach rock formation (see *Beach Rock*), and massive outcrops confer additional stability to a cay under erosive conditions. In contrast, spits at the ends of these islands are characteristically mobile and commonly shift from season to season. Mineralization of phosphates derived from guano has cemented sediments beneath the vegetation cover to form phosphate rock on some cays (e.g., Raine Island, GBR; Figure 7), also increasing island stability.

#### *Vegetated mixed sand and shingle cays*

Mixed sand and shingle cays may develop where wind direction shifts seasonally and shingle is supplied during

**Coral Cay Classification and Evolution, Figure 3** (a) Leeward unvegetated sand cay, Wheeler Reef, GBR. (b) Shingle cay with extended spit, Pandora Reef, GBR. one season and sand during the other (e.g., this process accounts for mixed sand and shingle cays in Torres Strait). Alternatively, shingle may be deposited during storms, with sand deposition during regular weather conditions. The latter mode appears to explain the sediment pattern of Lady Musgrave Island on the southern GBR. There,

shingle ridges have been episodically deposited by storm waves, with sand accumulating around the margins during normal trade wind weather. Mixed cays also develop where the character of sediments produced on the reef or delivered to the focal point of accumulation change through time, as may occur when reef geometry is modified or changing

sea levels modify reef flat hydrodynamics. In the atolls of the Caribbean, these mixed islands typically comprise a windward shingle ridge and leeward sand area. Lime and Hunting Cays are examples (Stoddart et al., 1982).

Reef islands deposited on atoll rims generally fall within this class, although the proportions of sand and shingle vary. On open-ocean atolls (see *Atolls*) in very low energy areas, e.g., close to the equator, islands may be predominantly sand but at latitudes where cyclones are more regularly experienced they tend to be dominated by shingle and boulders (see *Tropical Cyclone/Hurricane*). These linear shingle islands are generally larger than those found for example on barrier reef systems and are thus able to maintain a freshwater lens and diverse vegetation. Many of these islands have been home to Polynesian peoples for centuries or millennia and are commonly referred to as motu [Figure 3d; see *Atoll Islands (Motu)*].

#### *Vegetated shingle cays*

Vegetated shingle cays are uncommon. One Tree Island, Lady Elliot Island and East Hoskyn and Fairfax Islands (Figures 2d and 3e), all located at the southern end of the GBR, are among the few cays of this type to have been scientifically analyzed. However, Tomascik et al. (1997) suggest that they are probably common on the exposed parts of the Great Sunda Barrier in Indonesia. These cays typically develop near the windward margins of larger reef flats or centrally on smaller ones exposed to high energy. Most vegetated shingle cays are compact in form as linear shingle cays are usually either too narrow to retain adequate freshwater or too mobile for vegetation to endure. Where vegetation survives, the greater stability of the shingle cay allows vegetation succession to proceed until cyclonic disturbance occurs (Hopley, 1982). Observations from the atoll of Ontong-Java suggest that in areas of episodic high-energy storms and sufficient sediment supply, these cays may go through cycles of destruction, reformation, and revegetation (Bayliss-Smith, 1988). Stoddart et al. (1982) noted the mobility of these cays in the Caribbean, where substantial changes were recorded at North Spot and Rugged Cays between 1960 and 1972.

Hopley (1982) suggested that shingle cays developed from shingle ramparts, with the “tongues” of shingle and rubble that commonly trail leeward from ramparts also possibly involved; One Tree Island in the southern GBR has formed this way. The near concentric shingle ridges at Lady Elliot Island similarly document its formation over several millennia by the progradation of shingle ridges deposited during episodic storms (Chivas et al., 1986). However, as noted above, evidence from various locations suggests that storms may also destroy these features.

#### *Mangrove islands*

In low energy areas, mangroves may colonize reef flats (Figure 2e) and encourage sediment accumulation and island formation. Sediments deposited beneath the

mangroves vary from peats to carbonate mud. Mangrove islands are rare on the GBR, but are more common in Torres Strait (Hopley, 1997) where despite a relatively high-tide range mangroves more frequently develop in sheltered areas behind shingle ramparts. Similarly, reef top mangrove islands are reported from various locations in Indonesia without rampart protection but where low-energy conditions prevail due to proximity to the equator and associated benign wind regime [e.g., Pulu Panjang in the Berau Islands (Tomascik et al., 1997)]. They are common on reefs lacking windward ramparts in the Caribbean (Stoddart and Steers, 1977), but are generally restricted to high reef tops, areas of low energy, and areas of relatively low tidal range. Mangroves are common on the reefs of Belize and are associated with different types of island (Stoddart et al., 1982). “Mangrove cays” are mud mounds with a simple covering of mangroves: “Mangrove cays with dry sand areas” have featureless low lying sand areas within the mangroves; “Moat Islands resemble the low wooded islands of the GBR; and “Mangrove range” are complex and extensive arrays of mangroves with intermittent sand ridges especially on the windward side (see also Woodroffe, 1995). Mangroves are also common in sheltered locations within the three offshore atolls (e.g., Murray et al., 1999). In Florida Bay, mangrove islands began to accrete as the shallow Miami Limestone was flooded in the late transgression, with various models proposed to explain the location and processes of formation. Recent geochronological and lithological investigations suggest net accumulation punctuated by erosion episodes over the past few thousand years as the rate of relative sea-level rise slowed to its present position (Oches et al., 2009) (see *Mangrove Islands*).

#### *Multiple islands*

Multiple vegetated islands on a single reef are rare on the GBR; there are just two long-standing examples – Fairfax (Figure 3e) and Hoskyn Islands in the Bunker Group. Each includes both a vegetated shingle and vegetated sand cay on a single reef platform, shingle cay to windward, and sand cay to leeward (Figure 2d). On large reefs subject to seasonal reversal of winds but only rare storms, sand cays may develop at opposite ends of the platform; this appears to be the case at Masig-Kodall (Yorke Island) in Torres Strait (9°45'S) where seasonally reversed waves interacting with an unusually shaped reef produces two depositional nodes and islands. The same process is probably responsible for the occurrence of multiple islands in the Indonesian Archipelago, where according to Tomascik et al. (1997, p. 819) they are “not a rare occurrence.”

#### *Low wooded islands*

The basic pattern of a low wooded island comprises a windward shingle cay, a leeward sand cay, and significant mangrove development over the intervening reef top (Hopley, 1997; Figures 2f and 3f; see *Low Wooded Islands*). This combination of features may occupy

a great proportion of the reef top, usually between 25 and 50% but up to as much as 75% (Stoddart et al., 1978a). The majority of “classic” low wooded islands on the GBR occur on relatively small planar reefs on the inner shelf (e.g., Low Wooded Island – 87.9 ha), but they can occur on larger reefs (e.g., West Hope Island – 315 ha) (Stoddart et al., 1978a). Shingle ramparts that grade upward from the reef flat and have steep leeward faces are encountered at varying distances from the windward margin. These ramparts frequently parallel the reef edge, but shingle tongues may trail toward the reef interior (see *Shingle Ridges*). Mangrove stands develop in the relatively protected area behind the shingle ramparts and may eventually expand to cover much of the reef flat. The degree of mangrove colonization was considered to reflect the stage of island development by some workers (Steers, 1937; Fairbridge and Teichert, 1947), but others contend the degree of protection afforded by windward structures is responsible (Stoddart et al., 1978c; 1982). Stoddart (1980) suggested that once the protection is provided, the extent and rate of spread of reef top mangroves varies markedly between reefs, and the mangroves are in fact opportunistic colonizers. Organic muds occur beneath the mangroves on some islands but elsewhere the mangroves grow over sandy reef flats. Fields of emergent fossil microatolls document the higher mid-Holocene sea level and later regression experienced by the planar reefs on which low wooded islands on the GBR have formed (McLean et al., 1978; Chappell et al., 1983) (see *Mid-Holocene*).

The leeward sandy cays are morphologically diverse. Some are small, ephemeral, and unvegetated but larger vegetated cays replete with terraced morphology also occur (e.g., Ingram Island). The characteristic complexity of low wooded islands ensures that they are a heterogeneous group. Stoddart et al. (1978a) distinguished four low wooded island types, *low wooded island with limited reef top mangroves and a separate sand cay* are most numerous. *Low wooded island with reef top mangroves extending between windward shingle and leeward sand cays* are also common, with Bewick Island on the northern GBR the type-example. “Turtle-type” low wooded islands lack the central reef flat, with shingle ramparts and conglomerates extending to the leeward cays (Figure 1). They are generally restricted to small reef platforms (<60 ha) where they occupy a large proportion of the reef flat. The final class described by Stoddart et al. (1978a) includes those that could not be assigned to the groups above. Hannah Island, a sand cay completely encircled by mangroves, provides an example.

A chronology for reef flat formation and low wooded island accretion on the GBR has been established by radiocarbon dating (see Hopley et al., 2007 for summary). The dates suggest that (1) many low wooded islands formed under higher sea-level conditions prior to 3,000 years ago; (2) there is no consistent pattern in the timing and order of shingle and sand cay development on different reefs; and (3) many low wooded islands were in place

or substantially developed by the mid-Holocene and exist in similar form today, suggesting stability in the longer term. However, comparison of the detailed maps of Low Isles and Three Isles in 1928–1929 (Spender, 1930) with those produced later show modifications to ramparts, mangroves and cays, indicating that change may be constantly taking place (Stoddart et al., 1978b; Frank and Jell, 2006). Although the most detailed descriptions of these islands come from the inner northern GBR, equivalents occur in other reef provinces and include Salt and Pigeon Cays in Jamaica, and the Snake Cays in Belize, where they are referred to as “moat islands.”

### Reef-island vegetation

Vegetation plays an important role in the evolution of coral cays, being integral to all classification schemes, and showing important changes through time (see *Coral Cays, Vegetational Succession*). Progressive accretion is expressed by “rings” of vegetation from low creepers and grasses growing on recently deposited carbonate sands immediately behind the beach, through a zone of shrub vegetation on young soils with minor organic content, to an internal climax vegetation of woodland or forest growing on mature soils (see *Soils of Low Elevation Coral Structures*; Figures 3c and 4). The vegetation itself, together with the developing soils contributes to stability. Erosional episodes with subsequent return to progradation may result in the shrub or woodland vegetation being exposed immediately behind the beach or with a new area of colonizing vegetation fronting the climax vegetation.

The initial establishment of vegetation and subsequent changes has a number of requirements. Colonizing vegetation requires a degree of stability and access to some rainfall or brackish water (Figure 5). Addition of organic matter to the raw carbonate sediments comes not only from the vegetation but also from bird guano as nesting and roosting birds become attracted to the cay. As noted,

**Coral Cay Classification and Evolution, Figure 4** Climax forest vegetation dominated by *Ficus benghalensis*, Soneva Fushi, Maldives.

**Coral Cay Classification and Evolution, Figure 5** Pioneering creeper vegetation, pantropical *Ipomea pes-caprae*, Rodrigues Island, Indian Ocean.

the presence of phosphatic cay sandstone (Figure 7) is indicative of mature vegetation and is an obvious source of nutrients for the higher plants (see *Phosphatic Cay Sandstone*).

The origin of the vegetation on islands that may be hundreds or even thousands of kilometers from continents or other coral islands and the structured similarity of the cay vegetation worldwide were enigmatic to early explorers and naturalists. However, it soon became apparent that the seeds of many of the plants float and reach remote shores via ocean currents. Other seeds are ingested by birds and excreted on the island, or attached to plumage, sometimes causing the mortality of the bird. In both cases, the seeds are deposited with an organic fertilizer. More recently, exotic plants have been brought to islands by early settlers (e.g., Polynesian voyagers) and in some instances became dominant over the original preexisting vegetation. However, the harsh environment of coral cays with strong environmental influences such as climate, water availability, soil, and nutrient limitations enforces pantropical controls on the success or otherwise of cay plants and is the ultimate reason for the structural similarity of coral cay vegetation worldwide.

Physiognomic similarities conceal what is a very complex flora. For example, atolls thousands of kilometers into the Pacific and Indian Oceans have plant lists ranging up to almost 300 species [Table 1; e.g., Kiribati, 290 species (Thaman, 1987)], even though nearly all coral cays and low reef islands are less than 6,000 years old. Also in spite of the isolation of many reef islands, they have very few endemic plants. The number of plant species is dependent on:

- (a) Island size (even for isolated atoll motus, this is an important factor)
- (b) Remoteness from other islands or most importantly continental land masses

- (c) The period of human occupation (and introduction of exotics)
- (d) The frequency of disturbances which can range from natural events such as cyclones or tsunamis to human disruptions for coconut plantations or nuclear weapon testing

Dispersal distance from other land masses may not be based on present geography, but instead could reflect land configuration and the distribution of island “stepping stones” present during glacial low sea levels. For example, on the northern GBR at the maximum of the last glacial the whole continental shelf was dry and mainland carbonate dominated shorelines would have stretched, for example, across the Gulf of Papua allowing the retention of a wide range of plants currently found on the cays. Present day reefs that are further off shore would, at that time, have been high limestone islands and whilst, for a short period, they may have been little or no land in the form of islands on the continental shelf, as reefs were initially drowned by the post glacial sea level (see *Holocene High Energy Window*), the nearby mainland would have been a permanent source of floating seeds carried out to the offshore evolving cays. Today, the islands of this area have 380 species of plants (Fosberg and Stoddart, 1991). In contrast, the reefs and islands of the southern GBR would have remained isolated from continental Australia, even at the maximum low sea-level stage. Today, these islands (the Bunker-Capricorn Group) support only 80 species, between 22 and 40 on individual islands (Stoddart and Fosberg, 1991).

The range of substrate types is also important in determining the number of species present on an island. Sand and shingle substrates have contrasting species lists but these are expanded if different types of cemented substrate such as conglomerate or phosphatic cay sandstone occur. This was one of the conclusions of Sauer (1982) in his comprehensive review of vegetation on the Cayman Islands with a focus on the unconsolidated carbonate sediments, the vegetation of which is equivalent to that of Caribbean cays. His conclusions are applicable across other Atlantic and Indo-Pacific reef islands.

Sauer noted the importance of introduced species that can contribute 50% of cay flora (Table 1). Indigenous cay flora have very poor defensive mechanisms and are easily displaced. For example, on Mopelia atoll in the Society Islands, 50 of 85 species are introductions (Sachet, 1983). However, introduced species, unless cultivated, can also quickly disappear. During World War II, 129 species were introduced to Canton atoll, but by 1973 only 14 persisted. Sauer also examined the distribution of coral island plants, noting that while endemics were few, the flora of Atlantic islands had many commonalities as did that of the Indo-Pacific. There is also a distinctive pantropical element. The best known of these is the coconut tree, *Cocos nucifera*, but away from its source area of South-east Asia, it is an introduction on most islands. Pantropical species are mostly dispersed as float seeds with the ability

to remain viable for at least 6 months. More often than not these pantropical species are part of the initial beachfront colonizing vegetation (Figure 5). Sauer (1982) noted 11 pantropical species on the Caymans, but many more occur in the Pacific. For example, of the 380 species listed for the northern GBR (Fosberg and Stoddart, 1991), 25 also grow on the Cayman Islands though a number may be introductions. Twenty-seven GBR species were also found on Jamaican cays (Stoddart and Fosberg, 1991) and 33 on the cays of Belize (Fosberg et al., 1982).

Many questions remain unanswered about coral cay vegetation. Although apparently simple, with a classic pattern of ecological succession, the highly successful mechanisms of dispersal reinforce at the species level, the global physiognomic similarities. However, even this ability does not answer all questions. As Sauer (1982) noted, the fossil record for this vegetation is very poor, though clearly going back until at least the Tertiary. It has thus become involved in plate tectonics and changes to global land masses, especially the isthmus of Panama, which now closes the link between Caribbean and the Indo-Pacific. While there are possibilities of some flora migrating around the southern tip of Africa, this would entail a long route outside the tropics. Today's pantropical species may be the last vestige of the more open Tertiary geography of meso-America.

### Age, evolution, and relationships to Holocene sea level

A foundation, usually a reef flat at or near to sea level, is necessary for reef-island formation, but it may be small and not yet sea level constrained (Hopley, 1997; Kench et al. 2005). The relationship between reef growth, sea level, and reef flat formation on a global scale is complicated by various factors including postglacial isostatic adjustments of the continents and ocean basins, which have produced broad geographic differences in relative sea-level history and especially when reef tops first approached the sea surface (Clark et al., 1978; Lambeck et al., 2002). Pirazzoli (1991) presents detail on these patterns (see *Glacio-Hydro Isostasy*), but the relative sea-level curves for most of the Pacific and the Caribbean and thus the potential onset of cay formation in these two provinces are very different. Modern sea level in the former was reached 6,000–5,000 years ago, in places rose 1–2 m higher and has then fallen to present, whereas in the Caribbean it has been rising throughout the Holocene but, slowing over the past few thousand years. Modern sea level has only recently been reached (Toscano and Macintyre, 2003). Further, at a more regional scale, isostatic influences driven by differential loading by postglacial transgressive seas can produce variable relative sea-level histories as deeper shelf edge areas subside under water load (delaying reef flat formation) and shallower inshore areas possibly upwarp (Hopley, 1983; Lambeck and Nakada, 1990). Other factors that influence when a reef reaches sea level and provides a base for

reef-island development include the depth from which the reef has grown and the size of the reef and its lagoon. Typically, reef islands are oldest where current sea level was reached early – in the mid-Holocene, where the reefs grew from shallow substrates and were thus sea level constrained earlier, and where they grew on relatively small reefs with smaller lagoons that were infilled more rapidly than those of larger reefs.

The relationships described above are demonstrated on the GBR, where stable vegetated cays are strongly associated with planar reefs; 41 of 43 are on planar reefs that grow above shallow pre-Holocene foundations (mean: 10.8 m) and are relatively small (mean: 4.1 km<sup>2</sup>). Planar reefs also have the oldest mean reef top age (~6,000 years), so that depending on where reef geometry and hydrodynamic conditions initially focus sediment deposition, cay formation could have begun 6,000 years ago (Hopley et al., 2007). In Hopley's (1982) evolutionary classification of reefs [see *Reef Classification*, Hopley (1982)], planar reefs represent a senile stage approaching the end of their growth trajectories. Significantly, most reef islands with any degree of permanence are found on these senile reefs though at the time of their initiation the reef could have been at an earlier state (even reef patches) and persisted through the mid to late Holocene period of lagoon infilling and reef flat extension. Thus, at the geological time scale the factors that promote the advance of reefs through the reef growth sequence are also important drivers of cay formation. Spender's (1930) hypothesis that reef-island formation is strongly influenced by relative sea-level fall and reef platform emergence was dismissed for more than five decades (Steers, 1937; Stoddart, 1965). However, the importance of hydroisostatic upwarping of the inner shelf in accelerating the development of reefs to planar stage and as a consequence improving reef-island accumulation and, possibly, preservation is now generally accepted for the GBR.

Most reef islands on the GBR and all low wooded islands are inside the zero hydroisostatic isobase. Emergent reef occurs beneath reef islands in many other settings (discussed below). Kench et al. (2005) suggested that some Maldivian cays began to develop prior to reef flat formation, and West Indian cays have formed where sea level has risen gradually to present since the mid-Holocene (Woodroffe, 2003). Radiocarbon-dated fossil microatolls underlie many of the reef islands which have been investigated on the GBR, suggesting that most of them developed after the reefs had reached sea level (see Hopley et al., 2007 chapter 10), but the occurrence of ~75 unvegetated cays on platforms close to sea level suggests that emergent reef platforms are not absolutely necessary. Reef islands on the Cocos (Keeling) Islands, Indian Ocean are also deposited over fossil reef flat that are made emergent by the falling late-Holocene sea levels (Woodroffe et al., 1999). Dickinson (2004) revisited the earlier ideas of Schofield (1977) and proposed that wave-resistant emergent palaeoreef flats strongly influenced the development of stable reef islands on many Pacific atolls,

but he acknowledged that less stable “unpinned” reef islands are common on reef flats that remain flooded by lower tides. These higher foundations that confer stability to overlying islands are not always composed of Holocene reef. Cays composed of or attached to Pleistocene reefal deposits, or occasionally eolianites (see *Eolianite*), are common in the Bahamas and offshore from British Honduras (Milliman, 1973).

Establishing precise chronologies for reef-island formation is difficult as radiocarbon dates age the death of the contributing organism and not the age of the deposit; in many settings, these two ages can be centuries or even millennia apart. If the radiocarbon chronologies are correct, rapid sand production, delivery, and cay deposition occurred on many planar reefs of the GBR between 4,000 and 3,000 years ago, with only relatively minor modifications since. Similar histories are reported from elsewhere (Kench et al., 2005; see Woodroffe, 2008), including for Warraber in Torres Strait where bulk sand ages suggest a growth chronology very similar to those of the GBR cays described above. However, AMS radiocarbon dating of specific skeletal components suggests that the mid-Holocene age may be an artifact of age determination on bulk sands; ages of molluscs indicate sustained incremental accretion of Warraber over the past 3,000 years (Woodroffe et al., 2007). This pattern of incremental development is observed on many reef islands across the Indo-Pacific, rather than rapid deposition in discrete periods or phases (Woodroffe, 2008). It is important to note that progressive sea-level change and island growth may modify sediment production, transport efficiency over the reef platform, and depositional nodes. For example, where sea level has fallen during the late Holocene, reduced reef flat depths may significantly reduce sediment delivery to leeward cays (Kench and Brander, 2006).

The central, oldest areas of cays may be indicated by the presence of mature vegetation and greater soil development (see previous section), although Woodroffe and Morrison (2001) found no clear relationship between soil development and age at Makin Island, Kiribati. Reef-island formation has not ceased, and new reef islands will form if reef growth and sediment production continues. Hopley et al. (2007) present average estimates of the time required to progress through this sequence on the GBR and emphasize that small shallow lagoonal reefs can transform into planar reefs in as few as 250 years. Thus, where sediment supply is adequate and reefs of suitable elevation, geometry, and energy exposure exist, reef islands may form quite rapidly.

### Factors influencing cay stability

There are many records of cays, including those with a mature vegetation cover, disappearing completely, both during storms and over longer periods of time. Lines of beach rock on numerous reef flats attest to the previous presence of a cay even where there may be no historical record. A number of factors are involved which may also

require consideration when assessing the future impacts of global climate change. For the 300 reef islands of all types found within the Great Barrier Reef Marine Park, Aston (1995) carried out a statistical analysis of the factors that contributed to stability. They varied with island type but included:

- (a) *Location on reef flat and size of reef.* The position of the cay on the reef flat is determined by wave refraction patterns, which on most small to moderate size reefs is toward the lee side. On large reefs and irregularly shaped reefs, the area of sand delivery may be less focused and broad areas of sediment deposition in the central reef flat may result. Any cay that forms will be highly mobile as small weather changes result in contrasting wave refraction patterns.
- (b) *Size of cay.* Reef islands may vary from a few tens of meters in diameter, to several kilometers. As it takes a considerable period for large bodies of sediment to accumulate, the larger islands are indicative of stability, requiring major changes in energy conditions to produce significant changes to the cay shoreline.
- (c) *Shape of cay.* Cays vary from oval to elongate. Oval cays represent a sediment body that has been constructed by the same energy conditions over a period of time and are the most stable. Linear cays, often with highly mobile spits on both ends, are by far the least stable with location and orientation of the spits often changing seasonally especially in monsoonal climates (Figure 8).
- (d) *Vegetation.* A degree of stability is required for a mature vegetation to take hold on sand cays. Very important is the availability of a freshwater lens associated with cays with a minimum width of ~120 m (see *Coral Cays – Geohydrology*). Vegetation is not only indicative of at least some degree of stability but also through the binding action of roots, the addition of organic matter to soils and protection from heavy tropical storms by the canopy, it adds further to the island stabilization process.
- (e) *Cementation.* Several cementation processes produce hard rock outcrops which retard erosion. Intertidally beach rock can form very quickly (Figure 6). Similar intertidal cementation can occur on shingle islands forming conglomerate outcrops. On older islands, which have had a mature vegetation for some time and which have been used as nesting or roosting sites for sea birds, the leaching of guano into the soil can result in the formation of phosphatic cay sandstone (Figure 7) at the water table.
- (f) *Sediment budgets.* Over time the delivery of sediments to the reef flat, and ultimately to the reef cay, can change. Initially when the reef first reaches sea level, its high proportion of coral cover may be producing calcium carbonate at rates up to  $10 \text{ kg/m}^2/\text{yr}^{-1}$ , though much of this goes into the infilling of irregularities in the maturing reef flat. Ultimately, the reef flat may become totally sediment covered with delivery of

**Coral Cay Classification and Evolution, Figure 6** Massive beachrock, so important for cay stability, Wilson Island, southern GBR.

**Coral Cay Classification and Evolution, Figure 7** Phosphatic cay sandstone formed from the leaching of guano, Raine Island, northern GBR.

sediment to the cay during this period of change declining significantly. This may be due to a reduction in the ability of waves to transport sediment to a focal point (see *Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity*) or to the stabilizing effect of reef flat sea grass or macroalgae (e.g., at Green Island GBR where eutrophication in the 1950s and 1960s caused an expansion of sea grass on the adjacent reef flat which prevented delivery of sand to the cay, see Hopley, 1982, pp. 333–335. Erosion of the cay has taken place subsequently).

- (g) *Platform height*. A fall in relative sea level since a cay first formed (due to hydroisostatic or other causes) can leave a cay “perched” on its reef flat. The effect is to greatly reduce the power of waves to deliver sediment which is now limited to only a small part of the tidal cycle. An erosional phase may result though a rise in

sea level may have the opposite effect (see *Climate Change: Impact of Sea Level Rise on Reef Flat Zonation and Productivity*). Kench and Brander (2006) give some Australian examples.

- (h) *Meteorological conditions*. Cay location and morphology are strongly influenced by ambient weather conditions including storms which occur on a regular basis, producing short-term cycles of erosion and aggradation. However, there are many examples of changing wind strengths and direction causing longer term changes to reef islands as wave refraction patterns across the reef flat are modified and the orientation of an island changes or its location is changed so that it now loses sand over the reef edge (see Hopley et al., 2007, Chapter 13.5.3).

### Coral cay dynamics

Coral cays, composed of largely unconsolidated sediments, are classic natural systems in a state of dynamic equilibrium. Any change to the cay formation process – weather conditions, sediment budgets, reef morphology, or ecology – will produce an immediate response in the cay. Sediments are easily moved and high-energy events such as storms or tsunamis can produce major changes. However, small but significant changes are constantly taking place, over single tidal cycles, seasonally, over periods of years to decades in response to climate fluctuations, or in response to high-energy events. Each of these time scales is examined below with the majority of examples coming from the GBR where many islands of all types have been the subject of monitoring programs and a comparative study of all 300 islands within the Marine Park has been undertaken (Aston, 1995).

- (a) Tidal cycle changes

Hopley (1981, 1982) measured beach profiles around islands and sediment movement on the adjacent reef flat using sediment traps (Hopley, 1981) at three contrasting sites on the GBR over periods of high spring tides of up to 5 days. The sites were at Wheeler cay (a small unvegetated sand cay) (Figure 3a), Bushy Island (a maturely vegetated cay with *Pisonia* forest) (Figure 3c), and Three Isles cay (the leeward vegetated sand cay of a major low wooded island). Results were much as expected, with the largest changes to the beach and greatest sediment movement on the adjacent reef at unvegetated Wheeler Reef and smallest at the partially protected low wooded island site of Three Isles cay (Table 2).

- (b) Seasonal changes

Monsoonal climates produce significant changes to coral cays. This is illustrated by Coconut (Poruma) Island in Torres Strait, a narrow island of about 40 ha (Figure 8). Bi-monthly surveys at 21 sites in 1996–1997 recorded great mobility in the terminal spits with an annual pattern of erosion during the summer north-westerly monsoon, but with a return of

sediment from the reef flat under the influences of the winter south-easterlies. However, this cay is close to the reef edge and a circulatory movement of sediment around the island does produce a small net loss of sand of about 20,000 m<sup>3</sup>, equivalent to about 1% of the island volume (Hopley and Rasmussen, 1998).

Cays of the Maldives are also under strong monsoonal influence with large gross changes (31–21% of beach area) in shoreline position between seasons,

reflecting significant reversals in sediment flux of  $9\text{--}23 \times 10^3 \text{ m}^3$  biannually (Kench and Brander, 2006). However, annual net change is small (2–15%) indicating the island is in dynamic equilibrium.

(c) Decadal changes

Longer term surveys from aerial photography and ground truthing can determine if there is a long-term trend in cay changes and the dimensions of these changes. On Raine Island (northern GBR), Gourlay and Hacker (1991) reported erosion of up to 20 m and accretion of up to 40 m between 1967 and 1990 at specific points around the shore as the cay became more elongate. Annual sand movement on this small vegetated cay was about 5,000 m<sup>3</sup>. On Warraber in Torres Strait, maximum net shoreline movements over a 20-year period were around 60 m and at Green Island near Cairns, about 50 m between 1945 and 1978 (see Hopley, 1982). In the Bunker-Capricorn Islands, Flood (1988) measured average shoreline movements of between 14 and 53 m between 1972 and 1986 with maximum changes of up to 116 m.

These decadal changes include responses to specific cyclonic events, but also reflect long-term variations to weather patterns. In Torres Strait, wind records between 1951 and 1992 show a statistically significant increase in winter winds from the south-east, and an increase in wind speed at about 1975–1977. Realignment and a change in shape has occurred on some cays. Similar changes took place in the Bunker-Capricorn Islands. Here the annual wind energy vector has oscillated within a 45° arc from south-south-east in the early 1960s to east-south-east

**Coral Cay Classification and Evolution, Table 2** Contrasting beach changes, reef-flat sediment movement, and cay migration: Wheeler Cay (unvegetated); Bushy Island (mature vegetated); and Three Isles (low wooded island cay)

|                                                            | Wheeler Cay | Bushy Island | Three Isles |
|------------------------------------------------------------|-------------|--------------|-------------|
| Range of mean wind speeds (ms <sup>-1</sup> )              | 2.0–7.5     | 2.5–10.5     | 7.5–13.0    |
| Mean daily beach change (cm)                               | 17.46       | 2.74         | 1.51        |
| Maximum mean daily beach change (cm)                       | 24.95       | 2.76         | 1.98        |
| Mean daily sediment trap recovery (g)                      | 531.1       | 204.2        | 22.8        |

| Recorded long-term migration (m)                           | 110         | ~40          | ~35         |
| Period                                                     | 1975–77     | 1936–74      | 1929–73     |

<sup>a</sup>This is the maximum mean recovery from all traps set. Individual traps have recorded up to 4,063 g on a single day on Wheeler Cay.

**Coral Cay Classification and Evolution, Figure 8** Seasonal fluctuations in shoreline position, Poruma Island, Torres Strait.

in the 1970s, sufficient to cause some of the shoreline changes experienced during this period (Flood, 1986).

(d) High-energy, low-frequency events

Cyclonic events can cause erosion or accretion on reef islands depending on the tidal conditions and sediment availability at time of impact. If tides are high, erosion usually results; if low, then accretion may occur (Flood, 1986). Storm surges that exacerbate erosion on mainland sites have far less an impact on cays on offshore reefs, which generally lack the gradual shoaling of mainland bays and the funneling effect of coastal embayments. Many examples have been described from the GBR (Flood, 1980, 1981, 1986; Flood and Jell, 1977; Hopley, 1972). Cyclone Emily (1972) with a central pressure of 985 hPa produced surge levels >2 m on the Queensland mainland near Gladstone, but only 0.8 m as it passed over offshore Heron Island (Hopley, 1972). On nearby One Tree Reef, around 27 m of rubble was added to the ramparts on the southeast side of the island as this cyclone struck at low tide. In contrast, Cyclone Winifred (982 hPa) in 1986 passed over Green Island at high tide producing 70 m of erosion on the unstable spit. At low latitudes where the Coriolis force is insufficient to generate mature cyclones, swell waves from cyclones at slightly higher latitudes can still affect island shores.

Tsunamis can be experienced in many reefal areas. The 2004 Indian Ocean event (see *Tsunami*) caused washovers in several island groups (e.g., Maldives, Chagos) and although leaving erosional scars of up to 2 m and depositional sand sheets extending inland, the overall geomorphological impact was not as great as might have been expected.

All of these natural changes can be exacerbated by anthropogenic activities (see *Infrastructure and Reef Islands; Engineering on Coral Reefs with Emphasis on Pacific Reefs*). Groynes, rock walls, boat channels, and changes to reef flat ecology can all result in changes to beach morphology and sediment budgets with erosion being the most common result.

### Future for reef cays

Cays are dynamic landforms that are mostly low and composed of unconsolidated sediments. They are widely perceived as particularly vulnerable to climate and sea-level changes projected as imminent consequences of anthropogenic activities (IPCC, 2007). Some believe that they are more resilient – that their dynamic nature will allow them to adjust. Some of the key potential impacts of sea level and climate changes on reef islands are schematically represented in Figure 9 and discussed further below.

### Sea-level rise

Early concerns that sea-level rise will simply drown reef islands are now considered oversimplistic, with island response reflecting the complex interplay of numerous

physical, biological, and chemical factors. On some reefs, rising sea levels will allow larger waves to propagate further through more of each tidal cycle, increasing the transport of available sediment to islands. On reef flats affected by falling late Holocene sea levels, sediment deposits have accumulated and these may be mobilized shoreward – Hopley (1996) suggested that a sea-level rise of just 0.5 m would achieve this on many reefs. Hopley (1996) also modeled carbonate budgets for an idealized reef flat affected by a 0.5-m and 1.8-m rise by 2100 and showed that under the lower rate almost the entire reef would vertically accrete and reef morphology would not significantly change (see *Climate Change: Impact of Sea-Level Rise on Reef Flat Zonation and Productivity*). However, at the higher rate the algal zone transformed to coral cover, markedly increasing calcium carbonate production. The enhanced carbonate productivity would yield sediments suitable for reef-island construction, and because greater depth improves shoreward sediment transport, Hopley concluded that faster sea-level rise at first may be more beneficial for reef-island sustainability than a slower rate. Many reef geomorphologists agree that projected sea-level rise will substantially rework unconsolidated sediments and initially maintain reef-island mass (e.g., Kench and Cowell 2002).

The issue is more complicated, however, as elevation is critical on these low islands. Cay buildup is largely controlled by the characteristics of waves reaching the beach, with berm height – the height of the beach above mean high water – dependent on wave run-up. In a detailed study at Raine Island, Gourlay and Hacker (1991) found that the berm height was controlled by the wave run-up during the highest spring tides and calculated that the island may vertically accrete by an amount larger than the sea-level rise if reef flat aggradation lags behind the rate of sea-level rise and larger waves can reach the beach. However, given the diversity of reef-island morphologies, evolutionary histories, geographical settings, and human pressures, the future for reef islands may be diverse.

Late-Holocene emergence which has been demonstrated to be important to the formation and longer term stability of at least some cays has been discussed above. These factors would lose their influence as sea level increases. Uncertainties exist about future changes in storm frequency and intensity, but increases in both are possible. Higher wave energy might increase shoreline erosion, increase the frequency of inundation events, and threaten the quality and maintenance of groundwater aquifers and the long-term habitability of many reef islands. On Pacific Ocean, Indian Ocean, and Caribbean reef islands, settlements and vital infrastructure are almost without exception located close to the beach, where they are vulnerable to inundation, erosion, and other coastal hazards that may compromise the socioeconomic well-being of island communities. Understanding of some aspects of these interactions has advanced remarkably in recent decades. However, significant gaps still exist which limit capacity to confidently predict the long-term future

**Coral Cay Classification and Evolution, Figure 9** Schematic summary of potential climate and sea-level change impacts on reef islands.

of many reef islands. For example, simple models developed for linear and siliciclastic shorelines cannot be directly applied to reef islands.

### Reduced carbonate production and ocean acidification

There is heightened concern that thermal stress due to global warming (see *Climate Change: Impact on Coral Reef Coasts*) and changes in ocean pH associated with fossil fuel use (see *Ocean Acidification, Effects on Calcification*) is reducing both the amount of calcium carbonate produced on reefs and the durability of the sediments, both of which have the capacity to influence reef sediment budgets and ultimately the availability of sediments to maintain and build reef islands. The intensity and scale of coral bleaching has increased markedly since the 1960s, with entire reef systems affected by major events in 1998 and 2002 (see *Temperature Change: Bleaching*). Bleaching events not only affect corals, but also affect other photosymbiotic organisms such as foraminiferans that are very important contributors to many reef islands (Yamano et al., 2000). Calcification rates for corals on the world's best-managed reef – the GBR – are projected to decline by 14% compared to 1990 (D'earth et al., 2009) and it has been further

projected that coral cover will decline on reefs beyond 2050 (Hoegh-Guldberg et al., 2007).

Some reef islands accumulated most of their mass long ago, and these islands – especially if large and partially lithified – may be less sensitive to reduced carbonate production and ocean acidification in the short term. They will, however, be less able to dynamically adjust to projected changes in sea level and inundation. Where reef islands are younger, more mobile, and generally on less emergent reef flats, the future looks even less positive as active carbonate production and reef-island accumulation are more tightly coupled on lower reef flats, with efficient transfer of products to the zone of accumulation. In these circumstances, diminished carbonate productivity and sediment supply will probably have more immediate effects on island sediment budgets, morphologies, and prospects.

## CORAL CAYS – GEOHYDROLOGY

Kevin E. Parnell  
 James Cook University, Townsville, QLD, Australia

### Synonyms

Atoll island hydrology; Reef island geohydrology

### Definition

The geohydrology of coral cays relates to the movement of water through the island and reef framework under coral cays, particularly with respect to the characteristics of the freshwater resource resulting from density differences of freshwater and saltwater as affected by the composition and permeability of the reef framework in the context of its evolutionary history.

### Introduction

The earliest work on geohydrology applicable to coral cays was undertaken separately by Ghyben and Herzberg in the late 1800s and early 1900s, who determined the shape and thickness of a freshwater lens that forms under coral cays once they reach a minimum size. The relationship, which is based on the different densities of freshwater and saltwater, is expressed in the Ghyben–Herzberg equation:

$$z = \frac{\rho_f}{(\rho_s - \rho_f)} h,$$

where  $h$  is the distance above sea level to the water table (phreatic surface),  $z$  is the distance below sea level to the freshwater–saltwater interface, and  $\rho_s$  and  $\rho_f$  are the densities of saltwater and freshwater, respectively. Using densities of  $1.00 \text{ g cm}^{-3}$  for freshwater and  $1.025 \text{ g cm}^{-3}$  for saltwater gives the often quoted relationship

$$z = 40 h.$$

The Ghyben–Herzberg model makes an assumption of a single layer homogeneous medium, and a system in hydrostatic equilibrium, with no mixing of fresh and salt water, giving a sharp transition between the freshwater

and saltwater. This model is normally implemented with the Dupuit assumption of horizontal flow (Oberdorfer et al., 1990) and is frequently applied in resource assessments of potable water for human use on inhabited coral cay islands.

In reality, this model makes assumptions that are clearly not valid in most coral reef environments. Tidal fluctuations of the water level are assumed to be negligible, water movement within the lens is assumed to result entirely from recharge-induced changes to the hydraulic head, outflow from the freshwater lens required to maintain mass-balance is assumed to take place at the island margin, and mixing within the framework caused by various water movements and pressure gradients (such as tidal mixing) is not considered. Perhaps most significantly, the assumption of a homogeneous medium rarely holds. In particular, differences in the reef framework above and below the Pleistocene solution unconformity (sometimes called the Thurber discontinuity) typically found 6–25 below the current reef flat level in tectonically stable areas, means that the model is fundamentally flawed. In general, a very broad transition zone between fresh and saltwater can be expected.

### The dual aquifer model

The framework below the Pleistocene unconformity is typically highly karstified with high porosity and permeability, due to exposure during much of the period since the last interglacial approximately 120,000 years ago (Vacher, 1997). Seawater can move effectively through the karstified framework, effectively truncating the freshwater lens at the unconformity (Figure 1). The hydraulic conductivity of the Holocene framework is probably 1 or 2 orders of magnitude less than that of the Pleistocene framework (Oberdorfer et al., 1990; Woodroffe and Falkland, 1997).

A two-layer (dual-aquifer) model with a moderately permeable Holocene reef framework overlying a high-permeability Pleistocene aquifer, proposed by Wheatcraft and Buddemeier (1981) has been developed and used by others in modeling and investigations of cay groundwater resources (Ayers and Vacher, 1986; Herman et al., 1986; Oberdorfer et al., 1990; Underwood et al., 1992; Griggs and Petersen, 1993; Bailey et al., 2009; and others). These studies have found a quantitative agreement between model results and physical and chemical field data, giving some confidence in the approach. Tidal flow through the Pleistocene framework has been shown to be particularly significant, overwhelming any density differentials that may limit mixing in the Pleistocene aquifer. Short-term vertical water movements of 1 m or less driven by horizontally directed (in the Pleistocene aquifer) and vertically directed (in the Holocene aquifer; Herman et al., 1986) tidal pulses control the nature of transition zone mixing (Underwood et al., 1992). Other short-term climatic events, such as storms, can also be reflected in water movements that cause mixing in the reef framework. Clearly, the use of the Ghyben–Herzberg–Dupuit model

**Coral Cays – Geohydrology, Figure 1** The Ghyben–Herzberg lens of freshwater truncated at the Pleistocene unconformity due to the highly karstified nature of the Pleistocene reef framework (Hopley et al., 2007).

leads to a significant overestimation of freshwater resources on almost all coral cays (Oberdorfer et al., 1990). Bailey et al. (2009) highlight the importance of cemented layers confining the freshwater in the Holocene aquifer. These occur at the reef flat surface, forcing freshwater to discharge in fractures in the cemented layer, or elsewhere on the reef. Hard layers at depth can direct flow, or otherwise confine flow.

### Lens thickness and freshwater resources

The thickness of the freshwater lens is typically in the order of 10–20 m on small coral islands (Falkland, 1993), although thinner lenses clearly exist on small islands, and thicknesses of up to 30 m have been measured. The shape of the lens may be asymmetric, typically deeper on the lagoon side of atoll islands (Falkland, 1993), probably due to the preferential accumulation of lower permeability sediments on the lagoon side (Anthony et al., 1989). Anthony (1997) notes that the position of the island on the reef flat, specifically with respect to the prevailing wind is an important determinant of the thickness of the freshwater lens, due to leeward reefs typically having finer subsurface deposits than those on the windward side of the reef platforms. The lower permeability deposits on the leeward island support thicker freshwater lenses than those on windward islands (Bailey et al., 2009). It is suggested by Bailey et al. (2009) that whereas the freshwater lens on leeward islands is truncated at the Pleistocene unconformity, the lens on the (typically smaller) windward islands may not extend to that level. From a number of examples drawn from the literature, windward island lens thickness is in the order of 2–11 m, compared to 12–20 m for leeward islands.

Numerical simulations using the dispersion (as opposed to sharp interface) model SUTRA (Voss and Provost,

2003) presented by Bailey et al. (2009), show clear relationships between recharge, hydraulic conductivity, depth to the Pleistocene unconformity and island width, and the thickness of the freshwater lens.

The lens thickness and consequent water availability (White et al., 2007) can be significantly affected by climatic events, particularly drought. Bailey et al. (2009) simulate El Niño conditions showing that a 6-month drought required a 1.5-year recovery period for the aquifer for islands in the western Pacific.

Modeling presented by Oberdorfer and Buddemeier (1988) show that the dual aquifer may have a significant influence on freshwater resources during times of climate change and rising sea levels. Counter-intuitively, because the depth of the freshwater layer is frequently truncated at the Pleistocene unconformity, a higher sea level may increase total freshwater resources, by opening up more lower permeability sediments for freshwater storage, as long as there is not a coincident loss of island area.

### Summary

The Ghyben–Herzberg model is generally inappropriate for the examination of the geohydrology of most coral cays due to the presence of high permeability reef framework below the highly karstified Pleistocene unconformity. A dual layer model, used by numerous authors has provided a good understanding of water flow and of freshwater resources under coral cays, with dominant horizontal saltwater flows through the Pleistocene framework truncating the freshwater lens, with tidally driven vertical movements through the lower-permeability Holocene framework, to which the freshwater lens is confined. The actual thickness of the freshwater lens is dependent on a number of variables, the most important of which is sediment permeability. Dual layer dispersion models are

being used to adequately describe water flow and the freshwater resource dynamics of coral cays.

## CORAL CAYS, VEGETATIONAL SUCCESSION

Harold Heatwole

North Carolina State University, Raleigh, NC, USA

### Definition

Succession: A series of biotic communities replacing each other in an ordered temporal sequence, with each community creating conditions leading to the establishment of its successor.

Aeolian: Having to do with the wind.

Allochthonous: Coming from a source external to an ecosystem, community, or area.

Washover: The sea washing over an island during a storm.

### Early colonization

Continental islands have vegetation similar to that of and derived from the adjacent mainland. By contrast, cays have a much more limited subset of mainland floras, filtered by the vagaries of overwater dispersal; however, even for those, vegetation varies from sparse herbs, vines, and grasses to tall, dense forests. The present treatise deals with the causes of that variation and the temporal sequences through which cay vegetation pass.

The course of succession on cays depends on the type of substrate initially present. There are three main types associated with modern coral reefs. Sand cays begin as submerged sand bars that gradually accrete and eventually emerge from the sea. Rubble (or shingle) cays are formed suddenly by material from the reef being broken off and heaped onto the reef flat by a storm. In both cases, bare surfaces of sand or pieces of coral are exposed subaerially ([Figure 1](#)) and are available for colonization by terrestrial plants and animals, via some form of over-water dispersal. Mangrove cays differ in that plant succession begins before the cay itself forms. Propagules of mangroves are sea dispersed and take root in shallow water on reefs where they grow into trees. Dead leaves and other organic debris from these trees accumulate around the roots and eventually build up an organically rich mud that may in time become emergent above sea level. Some islands, of course, may be composites of more than one of these types.

Surprisingly, the first successful colonizers of bare cays may be animals, rather than plants. On the Great Barrier Reef of Australia, there are a number of sand cays, completely devoid of vegetation, that nevertheless have a fauna of up to 11 species of terrestrial invertebrates (Heatwole, 1971) such as flies, beetles, earwigs, mites, and isopods that subsist on dead marine organisms washed onto the beach, the carrion of marine intertidal invertebrates, and the excrement or cadavers of seabirds nesting on the island. On some cays, there are, in addition, predators such as centipedes and spiders, that feed on these terrestrial invertebrate scavengers. This assemblage thus depends either directly or indirectly on energy and

**Coral Cays, Vegetational Succession, Figure 1** Stages in the succession of vegetation on cays on the Great Barrier Reef of Australia. Top: bare sand cay; dark objects in the foreground are pumice (Bylund Cay, July 1988). Second from top: pioneer vegetation (Lady Elliott Island, 1969). Centre: cay with herb meadow (Bell Cay, July 1982). Second from bottom: savannah zone (Heron Island, January 1971). Bottom: Forest of *Pisonia grandis* (Northwest Island, July 1992). Photographs by Harold Heatwole.

nutrients from allochthonous marine sources, rather than from insular terrestrial ones. The organisms, such as sea-birds or crabs that connect the marine and terrestrial ecosystems and relay food from one to the other are known as “transfer” species.

The first plants to become established on bare cays are called “pioneer” species. They are usually transported there as seeds carried by sea currents. Many have special adaptations that improve their chances of dispersal in this way, such as devices that keep them afloat for long periods of time. In addition they need to be either impervious to seawater or resistant to high salinities. Not all species of seeds that are transported by water, however, are capable of becoming established on a bare island. Indeed, the beach wrack of many islands contains abundant seeds of species that have floated ashore but are not otherwise represented in the flora, either because the seeds did not survive the voyage, or because they were unable to germinate under the conditions they encountered upon arrival (Smith et al., 1990).

The successful pioneer species are those that combine the qualities of being able to withstand high salinities and salt spray, scarcity of water, shifting sands, low levels of nutrients in the soil, high temperatures, and bright sunlight. These are the conditions found on bare cays. The earliest pioneer vegetation consists of low herbs, grasses, and vines, often of a creeping habit (Figure 1). Species that put out runners over bare sand with roots descending at intervals are adapted to life on a shifting substrate as they tend to stabilize the sand. In time, pioneers may spread and cover much of the surface of a bare cay.

### Peripheral zone of shrubs

A few widespread, tropical shrubs, such as *Scaevola taccada* and *Suriana maritima* constitute a special category of pioneers. Perhaps the best example is Octopus Bush, *Argusia argentea*, a shrub/tree that is widely distributed throughout the Pacific and Indian Oceans. It has a buoyant corky layer around the seed that keeps it afloat for many weeks. It can survive for long periods at sea and in fact the seeds, although not germinating in seawater, germinate better after exposure to seawater. Seeds of this species are dispersed by sea currents over thousands of kilometers to be cast ashore on some remote island where, under the influence of rainwater, they germinate on the upper beach (Lesko and Walker, 1969).

These plants add a new zone of pioneer vegetation by forming a ring of shrubs that encircles the island (Heatwole, 1994). Octopus Bush is mainly on the upper beach as it seldom disperses even a few meters inland because seeds dropping from the parent tree have not been exposed to seawater (Figure 2). Where this shrub is found further inland it often is because the beach has extended since the plant became established. Once a shady, peripheral ring of shrubs has formed, it ameliorates conditions such that other sea-dispersed shrubs and trees find favorable germination sites.

**Coral Cays, Vegetational Succession, Figure 2** Zonation of vegetation on a cay on the Great Barrier Reef (Northwest Island, July 1992). There is a band of pioneer vegetation (*foreground*). The shrub "ring" is represented by a single young Octopus Bush (*Argusia argentea*) at high-tide line and a nearly continuous ring of older, tall Octopus bushes on an older level of the upper beach (*middle ground*; darker green), bordering the *Pisonia grandis* forest (*background*; lighter green). Note the recent erosion of the upper beach. Photograph by Harold Heatwole.

### Herb meadows

Pioneer species stabilize shifting sand, shade the surface of the ground, and through adding dead leaves and other organic matter enrich the soil (Wiens, 1962) and begin to form a soil profile. In addition, the shrub ring serves as a windbreak, provides more extensive shade, and screens out salt spray. Providing sufficient fresh water becomes available, these changes facilitate inland conditions that are favorable for species that could not colonize a beach or a bare cay. Very small sand cays have little permanent fresh water but as they grow larger through further accumulation of sand, they surpass the critical size for retaining

rain as a lens of freshwater in the soil (Wiens, 1962). The stage is now set for the establishment of species of non-pioneer plants. Most of these new colonists are dispersed by birds, either attaching by hooks or sticky secretions to feathers of a variety of birds, including seabirds, or are carried in the digestive tracts of seed-eating or fruit-eating birds. Once deposited in their new home, they grow and form a meadow of herbs and grasses (Heatwole et al., 1981) (Figure 1). The pioneers either find the new conditions unfavorable to them, or are out competed by the new arrivals and they decline, leaving the center of the island covered by the second wave of colonists. The cay is now zoned, with pioneer species still dominating the upper beach, followed behind by a shrub ring and with a central meadow of herbs and grasses.

### Savannah

With increasing bird traffic attracted to the greater plant cover in the interior, the number of species of plants there builds up, including a variety of trees and shrubs that shade the island's central habitat still further and contribute greater amounts of organic matter to the soil. In this way the herb meadow becomes dotted by scattered shrubs and trees to form a savannah (Figure 1), sometimes called parkland. Trees that are common in the savannahs on cays are *Cordia subcordata*, *Calophyllum inophyllum*, *Hernandia peltata*, and *Guettarda speciosa*. Humans have often contributed to this zone by plantations of coconuts (*Cocos nucifera*).

### Forests

Over time, the density of arborescent vegetation increases until a forest forms, complete with a ground cover of leaf litter and a more mature soil profile. Species of sea birds, such as the Black Noddy (*Anous minutus*) that require trees for nesting, roost in large numbers in these forests and contribute massive amounts of guano to the soil. Most species of low vegetation of the herb meadow or savannah cannot tolerate the dense shade and high nitrogen levels under the forest and accordingly they disappear, leaving only a sparse cover of nitrophilous plants. Now, the zonation includes a peripheral ring of pioneer species surrounding a shrub ring, with the interior of the island covered by forest or a combination of forest and savannah. All of these stages in the succession of vegetation can be seen on islands on reefs (Figure 2). The forested islands seem to be the end stage in this sequence as no further stages have been witnessed. This does not mean that change ceases, however, or that all islands inevitably reach this final stage. Because of that, some ecologists dispute the validity of the concept of succession. Further changes, however, can be viewed as intervention by forces or agents that halt or reverse what would otherwise be an orderly progression. Some of these retrograde, destructive influences are known (Heatwole, 1984) and are as follow:

**Coral Cays, Vegetational Succession, Figure 3** Gannet Cay, Great Barrier Reef (January 1989), a cay that was once much larger and with a well developed herb meadow. It was formerly located farther onto the reef, toward the top of the picture. The automatic weather station seen in the center of the picture was once located in the center of the island. The island has now shifted to the edge of the reef and is losing sand to deeper water as seen by the cascade of sand toward the left end of the island. Photograph by Harold Heatwole.

### Erosion

The pattern of zonation of vegetation, described above, can be obliterated by erosion. As direction of prevailing winds shift, or local patterns of sea currents change, beaches on one side of an island may erode and encroach into a herb meadow or even a forest. Often, the beach on the opposite side of an eroding island is prograding and widening the zone available for pioneer vegetation. Thus, instead of concentric vegetation zones, they are off center and lopsided. In extreme cases, cays can move across the reef, eroding on one side and prograding on the other, until eventually, the position of the cay scarcely overlaps that of its former location (Flood and Heatwole, 1986), or a cay may go over the edge of its reef into deep water and disappear altogether (Figure 3).

### Marine washover

Severe storms may result in a cay being washed over by waves and the terrestrial vegetation destroyed (Flood and Heatwole, 1986), with succession having to start over again. The history of some islands can be seen in heavily eroded beaches where dark layers of humus (indicating previous times of vegetation cover) are interleaved with layers of light-colored sand (left from times when the island was devoid of vegetation, either because of marine washover or from Aeolian deposition of sand on top of the plants) (Figure 4).

### Seabirds

The role of seabirds as transfer organisms, as dispersers of seeds, and as enrichers of the soil, has already been discussed. Birds may also have a destructive effect. Where

**Coral Cays, Vegetational Succession, Figure 4** A highly eroded beach on Frigate Cay (July 1987) showing alternating layers of dark organic humus and lighter-colored sand, representing successive periods of vegetation cover and bare sand at the surface. Note that encroachment on the herb meadow by erosion has exposed roots of *Boerhavia diffusa* (upper left).

they nest on a herb meadow in large numbers, their trampling may destroy plants (Heatwole, 1984) and return the island to a previous stage, or even to a bare cay. This is especially likely to occur if the breeding colony is being concentrated into smaller space by continued erosion of an island on one edge of its reef, while the prograding side goes over the edge into deep water.

### Sea turtles

When sea turtles come ashore to nest, the female digs a pit in which she lays her eggs; in the process she may kill plants by uprooting them (Figure 5). Species of the herb meadow are more susceptible because they usually occur as individually rooted plants. By contrast, many pioneer species have runners with multiple root systems, so that even if a large part of the plant is dug up other parts of it

**Coral Cays, Vegetational Succession, Figure 5** Nesting sea turtles dig pits in the sand in which they lay their eggs. This activity leaves an uneven terrain of hummocks and pits, as seen in this photograph. The uprooted vegetation dies (*foreground*). Such destruction by turtles can lead to return of herb meadow (without creeping plants) to pioneer vegetation that is anchored over a wide area by runners. Photograph by Harold Heatwole.

still have roots in the soil and the plant can survive. For this reason, where turtles nest in high numbers, succession may be halted or herb meadow even reversed to pioneer vegetation (Heatwole, 1984; Rogers 1989).

### Drought

Even in such an equable environment as a tropical island, the weather is not constant. There are year-to-year changes in the amount of rainfall, and these can affect the trajectory of vegetational succession on cays. There has been only one detailed study of this phenomenon and that was on One Tree Island at the southern end of Australia's Great Barrier Reef from 1968 to 1978 (Heatwole, 1981; Heatwole et al., 1981). Rainfall was plentiful for most of the time, but there was a drought of four months, that

killed a lot of vegetation. No species of plant went extinct because of the drought, but the most abundant species of the herb meadow (*Melanthera biflora*) declined to less than a quarter of its former biomass. By contrast, a pioneer species (*Ipomoea pes-caprae*) that had been rare in the herb meadow before the drought thrived and increased greatly in biomass to become the dominant species. Thus, the drought caused vegetation in the center of the island to revert to a previous successional stage.

### Humans

Humans have a major effect on cays, through direct destruction of vegetation and fauna, construction of buildings, mining guano, altering patterns of erosion, planting gardens and coconut groves, and introduction, intentional or otherwise, of weeds. Lady Elliott Island on the Great Barrier Reef is an example of both good and bad effects of humans. It was first nearly denuded by guano miners who destroyed the vegetation and stripped the soil. Later, it was restored to nearly its former condition by replanting native vegetation as part of the development of an eco-friendly resort.

### Summary

As a bare cay forms and increases in size, its vegetation goes through a predictable progression of successional stages: bare cay → pioneer vegetation → pioneer vegetation plus encirclement by shrubs → herb meadow → savannah (parkland) → forest. Plants of the earliest stages tend to be sea-dispersed whereas later the vegetation consists mostly of bird-dispersed species. The vegetation becomes progressively organized into concentric zones with earlier successional stages located peripherally and later ones successively toward the center. This sequence can be altered, or reversed, by various destructive forces, including trampling by seabirds, uprooting of vegetation by sea turtles, drought, erosion of beaches, washover during storms, and human activities.

### Definition

*Coral reef*: A tract of corals growing on a massive, wave-resistant structure and associated sediments, substantially built by skeletons of successive generations of corals and other calcareous reef-biota.

*Coral-algal reef*: A rigid wave-resistant structure in which scleractinian (stony) corals and crustose coralline algae are the dominant frame-builders. The term “modern” is used to refer to reefs that are forming or have formed in response to late Holocene sea levels (less than 7000 years B.P.) (James and Macintyre 1985).

### Introduction

Drawing a parallel with a definition of the coral reef's nearest terrestrial equivalent “forest” as “large tract covered with trees and undergrowth” (Fowler, 1929), “coral reef” could simply be defined as “large tract covered with corals and undergrowth.” However, these words fall well short of capturing a coral reef's total character on two major fronts (Stoddart, 1969): first, the notion that the organisms of the reef themselves do not simply cover a tract, but also contribute to its nonliving physical structure (Figure 1) in a way that has no parallel in forests; second, the rich and complex ecological systems of which the corals are part. Documentation of variation in form and process started with Darwin's (1842) recognition of oceanic fringing reefs, barrier reefs, and atolls as a developmental series on subsiding volcanic islands. Such reefs, whose surrounding water depths and thickness

exceed 1,000 m, represent the outcome of episodes of reef growth, punctuated by sea-level change, since the Tertiary (Hopley et al., 2007). Other impressive coral reefs are much thinner and much younger, exemplified by reefs on the shallowest parts of continental shelves that were >100 m above sea level as recently as 20,000 y BP and became inundated as recently as 7,000 y BP. There, water depths and reef thickness can be less than a few meters, the entire entity representing reef initiation and growth of the mid to late Holocene epoch (Kennedy and Woodroffe, 2002).

A terminology for coral reefs based on their relationship to land mass and depth of surrounding water (Figure 2c; see also James and Macintyre, 1985; Spalding et al., 2001) includes the following: “fringing reef” (a linear reef with a reef flat some tens of meters across, growing along shelving coastlines and across embayments); “bank barrier reef” (another form of linear coastal reef a little further from the shore than the fringing reef, and sometimes coalescing with one); “barrier reef” (also a linear structure, but fronting deep oceanic waters and broader – usually hundreds of meters across – and separated from the coastline by navigable waters); “atoll” (broadly circular reefs enclosing a wide lagoon); “bank reef” or “platform reef” (a substantial reef fitting none of the above categories, occurring in oceanic and coastal settings). Collectively, these terms account for most of the large scale morphological variability observed in tropical coral reefs. Coral reefs that are substantially built by skeletons of successive generations of corals and other calcareous reef-biota also exist in deep, cold waters (Roberts et al., 2006). However, these “cold-water coral reefs,” located at depths well below the impact of breaking waves, are not “wave-resistant” structures in the same sense as shallow tropical reefs.

Smaller scale morphological variability within and among reefs is very strongly determined by the “antecedent topography” on which corals established themselves (Shinn et al., 1977) – i.e., the location, shape and time of Holocene inundation of topographic sea-floor high points of stable substrata (e.g., rocks, fluvial rubble, fossil carbonate reefs or dunes). From the mid-Holocene to the present, primary colonization and the upward and outward accumulation of calcium-carbonate skeletons across that topography has adorned and obscured its shape to varying degrees. This transformation has been represented in whole reefs as a progression through a development series from “initiation” through “juvenile,” “mature,” and “senile” stages (Figure 1; see also entry *Reef Classification by Hopley (1982)*), a scaled-up manifestation of the series of local scale transitions “a” to “d” in Figure 1 and Figure 2a. In “resorbed” and “remnant” reef structures (see entry *Reef Classification by Maxwell (1968)*), “degenerative” processes have prevailed, as cumulative loss of reef material through storms and erosion (both biological and physical) exceeds accumulation of reef material; the net transitions have been in the reverse direction (e.g., “d” to “c,” “b” or “a”)

**Coral Reef, Definition, Figure 1** Reef growth model. Inset: Hopley's classification of shallow reefs according to their stage of Holocene development (shown as stipple; see also entry *Reef classification* – Hopley 1982). Main section: Local scale processes and events responsible for reef growth. (a) Primary coral colonization of newly available substratum and examples of types of substrata made available by last sea-level transgression: boulders (e.g., fluvial; littoral); bedded limestone or sandstone; fossil reef (pitted by subaerial erosion). (b) Incipient reef. Coral–algal framework with or without sediment infilling has developed over the substratum in (a). (c) All the corals and part of the framework have been torn off by storm waves and scattered on the adjacent sea floor, extending the colonisable substratum. One large massive coral remains intact and in place, and another has been thrown clear of the developing reef. (d) The surface of the incipient reef has been recolonized and further framework added, filling the space between the developing reef and the first massive coral, now much larger. The massive coral tossed off the reef in (c) died and has become substratum for more coral growth. It may in time be moved by another storm, and/or become incorporated into the developing reef. In shallow water, further upward growth of corals and hence the structure will eventually be limited by exposure to the air. In deeper water, further upward growth may occur, or it may be limited by destructive waves (see entry *Corals – Environmental controls on growth*).

The James and Macintyre definition of “coral–algal reef” (above) gives coralline algae equal prominence with stony corals, recognizing their role both in accreting thick algal ridges and in cementing coral skeletons together into a framework. Their definition works extremely well for oceanic reefs worldwide, in which the necessary resistance to powerful ocean waves is inconceivable without the major contribution made by coralline algae. However, the term “coral reef” is also used to describe coral tracts sitting atop accumulations of coral debris with little or no submarine cementation: e.g., cold water reefs (Roberts et al., 2006) and many tropical fringing reefs, shoals, mounds, and banks. This raises the question of whether these latter forms should be excluded and called something else, or included under a more generic definition such as the first one presented above. It would be difficult to apply the James and Macintyre definition – with its

emphasis on cementation by coralline algae – to many of the mega-diverse coral reefs in sheltered waters of South-East Asia (Spalding et al., 2001; see *East Indies Triangle of Biodiversity*), the Great Barrier Reef lagoon (Johnson and Risk, 1987; Hopley et al., 2007; Perry et al., 2008), or the rhomboid shoals behind the Belize Barrier Reef. The latter have been described in terms that could be used to describe reefs in sheltered waters in many parts of the world: little submarine cementation; corals stabilized by interlocking of their skeletons; colonies growing to the point of oversteepening and toppling down slope; debris fans at their base; only occasional storm disturbance (Aronson and Ellner, 2007). Lacking major cementation, and lacking exposure to the ocean's strongest waves, their wave-resistance is less in absolute terms than that of oceanic coral–algal reefs. They have, nevertheless, like “coral–algal” reefs, elaborated in the mid- to

**Coral Reef, Definition, Figure 2** Coral reef structure at scales of metres to 100s of kilometers. (a) Position of reef surface at stages “a” to “d” in Figure 1. Vertical arrows show accumulation (up arrows) and interruption of vertical growth by the storm in Figure 1c (down arrow). Horizontal arrows show the extent of lateral spread of colonisable substrata, providing the potential for the reef to “step out over its own debris” (Blanchon and Jones, 1997). (b) Profile of generalized coral reef exposed to waves from the right. The present reef surface has developed over the mid-Holocene substratum (dashed lines) by processes illustrated in Figure 1. (\* Note the five times difference between the vertical scales for coastal and oceanic reefs). The major growth directions, sediment movement and dominant environmental factors limiting coral growth and framework development are indicated: viz. light, sedimentation (rate of sediment fall), waves, tide (= exposure to air). (c) Diagram of some major reef types and bathymetric settings of coral reefs. Double lines indicate positions of cross-reef transects that could be represented by Fig. 2b. Contours indicate depths in meters. Continental shelf extends from coast to 100 m isobath.

late Holocene as structures widely referred to among scientists as “coral reefs.” Their smaller dependence on algal cementation and strong framework is evident in a number of modes of growth in fringing coral reefs (Kennedy and Woodroffe, 2002), in which lateral reef growth over unconsolidated coral debris is prominent. In summary, the first definition (see section ‘Definition’) is preferred here because it accommodates both the “classic” coral-algal reef style defined by James and Macintyre (1985) and also coral tracts established on less strongly consolidated substrata.

### Coral community: geological and ecological definitions

Further differentiation is provided by Buddemeier and Hopley (1988), who distinguish between “coral reef,” “coral reef community,” and “coral community.” They use “coral reef community” to refer to an incipient coral reef (Figure 1b) – not yet a massive wave-resistant structure, but on a developmental trajectory toward that state. Their “coral community” is on no such trajectory: it refers to a local assemblage of corals that are attached directly to nonreef substrata and provide no indication that their

predecessors have, or they and their successors will, substantially expand the substratum the way incipient reefs do. The state illustrated in [Figure 1a](#), assuming it was representative of an area of at least hundreds of meters, would be referred to as “just a coral community” so long the corals failed to add to a wave-resistant framework, either in situ or by ending up in a congruent rubble bank.

These terms are useful in placing “coral reef” on a “not-reef” to “reef” continuum, defined in terms of realized or potential “structure.” However ecologists use these terms differently: “community ecology” is a rich and long established discipline that focuses on environmental and biological drivers of “structure” in plant and animal communities (May, 1985). “Structure” in a community refers not to physical form, but rather to spatial pattern, species composition, population dynamics and the like. As a simple descriptive term within reef ecology, “a coral community” refers to the corals occupying a local area, irrespective of its substratum (e.g., Done, 1982), and a “coral reef community” refers to the entire ensemble of marine species that occupy a coral reef, and among which the “coral community” is a part. Coral reef communities are extraordinarily rich in species and co-evolved relationships, with important functional roles that facilitate tight recycling of nutrients in nutrient-poor waters (Hallock, 2001), survival in turbid seas (Perry et al., 2008a), and high per unit area productivity of protein, reef building blocks and sediments (Done et al., 1996). The terms “coral community” and “coral reef community” thus have contrasting nuances for earth scientists and biologists. However, their meaning will usually be clear according to the context in which they are used.

The measure of a good definition is the extent to which it eliminates similar entities. In the following sections, the definition is dissected and the terms elaborated using both examples and exceptions. [Table 1](#) describes some of the relevant terms.

### A tract of corals

Tracts (viz. “large areas of indefinite extent”) of living corals provide food and shelter for much of the abundance and diversity of marine biota for which coral reefs are renowned. In two circumstances, however, living corals are absent – or they are at least too sparse to be reasonably referred to as a “tract” – from what would still be considered legitimate contemporary coral reefs: “dead” and “marginal” coral reefs. In “dead” coral reefs, absence or scarcity of corals is a consequence of a recent (within a human life span) catastrophic impact (e.g., predation, disease, coral bleaching, cyclone). Regardless of whether the corals recover expeditiously (years to decades), this structure would still be considered a “coral reef,” albeit “dead,” or in an alternate or phase shifted state (Done, 1992; McClanahan et al., 2002). In “marginal” coral reefs, corals are sparse or absent from reef substrata because the supply of coral larvae or viable fragments no longer exists, and/or on-site environmental conditions have become inimical for corals. There are, for example, “drowned reefs” that supported flourishing coral communities before the sea-level transgression but where light is now limiting and sedimentation is excessive for good coral growth and survival. And there are back-reef areas for which the reef’s own growth has so greatly changed water circulation that

**Coral Reef, Definition, Table 1** Brief glossary of useful terms for describing generic characteristics of corals and coral reefs at spatial scales from <1 mm to hundreds of kilometers. An example of specific reef types is provided in [Figure 2c](#)

| Term/alternative                                              | Description                                                                                                                                                                                                                                                                                                                                                      |
|---------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Larva/planula larva                                           | Free living soft-bodied embryo that settles on a solid substratum and forms a primary polyp                                                                                                                                                                                                                                                                      |
| Primary polyp                                                 | The polyp into which the larva metamorphoses                                                                                                                                                                                                                                                                                                                     |
| Zooid                                                         | A polyp and its corallite                                                                                                                                                                                                                                                                                                                                        |
| Corallite                                                     | The limestone cup that is secreted by each polyp and provides it with structural support                                                                                                                                                                                                                                                                         |
| Corallum                                                      | The limestone skeleton of a coral colony                                                                                                                                                                                                                                                                                                                         |
| Colony                                                        | The limestone skeleton plus the living polyp tissue, produced by replication of the primary zooid and all its descendants.                                                                                                                                                                                                                                       |
| Population                                                    | All members of one species living in a defined area, such as a single coral reef. In a regional context, the single reef’s population is a “sub-population” of a regional “metapopulation.”                                                                                                                                                                      |
| Community/assemblage                                          | All colonies of all species occupying a defined area, such as a reef or a specific part of a reef                                                                                                                                                                                                                                                                |
| “Bommie” (Australian vernacular, widely used internationally) | 1. A “head” coral two to several meters high and across                                                                                                                                                                                                                                                                                                          |
| Patch reef                                                    | 2. A patch reef<br>A number of corals of one to many species growing on a discrete patch of reef substratum associated with a larger structure referred to as the “main reef” in <a href="#">Figure 2b</a>                                                                                                                                                       |
| Coral reef/coral reef complex                                 | See “Definition” (above) and “ <i>Coral Reef – classification</i> .” Its basal footprint (delimited by consolidated reef and adjacent sedimentary deposits) is usually measured in hectares or square kilometers. A coral reef always includes a discrete main section and often includes bommies and patch reefs in the footprint ( <a href="#">Figure 2c</a> ) |
| Reef tract                                                    | All contiguous and adjacent coral reefs within a particular region. Depending on commonality of the environment and the strength or weakness of material exchanges among them, the reefs in a tract may be considered to constitute a “system,” in which the state of one may influence the state of another                                                     |

regimes of temperature, oxygenation, salinity, and turbidity have become inimical for coral growth (Macintyre, 2007).

### Massive structure

A coral reef is “massive” (relative to the size of a human observer) in terms of both its basal area (usually hectares and upward) and its thickness (a nonliving basement usually meters to tens of meters thick and the living corals and diverse other sessile biota attached to it – usually <1 m to a few meters tall). Coral covered substrata of smaller dimensions than these could still legitimately be referred to as “coral reefs,” but so long as they were in close vicinity to a larger structure, they would generally be referred to as “patch reefs,” and considered to be a physically discrete part of the larger unit: e.g., the patch reefs at the back of such and such a reef.

A generalized picture of the “classic” reef-building processes based on James and Macintyre (1985) and Kan et al. (1997) is as follows: large corals of diverse and irregular shapes remain in place after their death, forming roofed-over cavities (robust branching forms such as *Acropora palmata* – James and Macintyre, 1985) or stacks of head and branching corals (Kan et al., 1997) – the whole becoming a “framework” that becomes inhabited by smaller attached calcareous benthos. Encrusting organisms (calcareous algae) grow over dead surfaces, aid in stabilizing the structure, and provide environmental cues that promote settlement of new corals (Harrington et al., 2004). Assuming there is sufficient water above (Figure 1; see entry *Accommodation Space*), another layer of corals can thereby settle, grow, die, become incorporated into the reef framework, and thus incrementally thicken the reef structure (Pichon, 1974; Kan et al., 1997). In stormy weather (Figure 1c), weakly attached or branching corals are broken, dislodged, and deposited in reef cavities and skeletal conglomerations on the reef slope or adjacent sea floor, allowing the reef to extend laterally by “stepping out over its own debris” (Blanchon and Jones, 1997). The latter process may be a result of settlement of coral larvae on the debris, or regeneration of still viable coral fragments among the rubble.

Another equally important process is infilling. The developing framework can be buried by or partially filled with sediment, with grain sizes from fine silts to coarse rubble, either before or after significant cementation has taken place. The types of corals, types of sediments, stage of cementation, and time and rate of burial produce distinctive layers in the sedimentary profiles of the reef (Shinn et al., 1977) that are reflected in distinctive limestone rocks in fossilized reefs (James and Macintyre, 1985; e.g., see entries *Rudstone*, *Bafflestone*, *Framestone*, *Floatstone*).

### Wave resistant structure

All coral reef definitions specify a structure that is highly resistant to wave impacts. Strong swells and waves do sometimes damage framework and cause catastrophic losses to reef biota (see entry *Tropical*

*Cyclone/Hurricane*). However, the change (in terms of tonnes of reef debris created and moved) is generally insignificant compared to mass and volume of reef framework that remain intact and in place. Moreover, the dissipation of wave energy across reef flats, the refraction of waves around reefs, and the flushing of sand through canyons by return flows are highly instrumental in determining the shape of reefs (Blanchon and Jones, 1997). Such a wave on reef interaction promotes the retention of reef-derived blocks, rubble, and finer sediments within the existing reef footprint, and thus the reef’s propensity to “step out.”

### Associated sediments

Coral reefs generate massive amounts of carbonate sediments. Fine sediments (sands and silts) are derived from both bioerosion of large metazoans such as corals, and the post-mortem disintegration of other calcifiers, notably foraminifera, small molluscs, and diverse segmented calcareous organisms including coralline algae and crinoids (James and Macintyre, 1985). Coarse sediments (boulders, blocks, rubble, shingle) are moved by storms, currents and gravity (see above and entries *Tropical Cyclone/Hurricane*, *Hydrodynamics of Coral Reef Systems*). They fall into lower energy deposition sites, including crevices within the reef, talus beds at the base of reef slopes, reef-flat boulder ramparts, sheltered back-reef lagoons and aprons, and gutters. In reefs far from land, most if not all sediments are generated by the reef. However, on some coastal reefs, sediments of terrestrial origin can dominate infilling sediments and the near-reef sedimentary apron (Kleypas et al., 2001; Larcombe and Carter, 2004). These imported sediments may include (1) sediments from the present-day land mass (via surface runoff, dust or ash) and/or (2) sediments from now-submerged mid-Holocene coastal low lands, re-suspended and swept into and around reefs by currents and waves (Larcombe and Carter, 2004).

### Substantially built by successive generations of corals and other reef builders

Over scales of decades to millennia, reef growth is dependent on ecological resilience in the resident stony coral populations and other reef builders – their capacity to recover dense populations following those necessary physical disturbances that transform some of them into debris. In a well functioning reef, “other reef builders” perform a number of direct and indirect “bioconstructional roles” in addition to the primary framework building role of stony corals and encrusting coralline algae (Done et al., 1996): “secondary framework builders” such as byozoans and bivalve molluscs and tube worms add small scale topographic complexity to the framework; microbes condition substrata for coral settlement and contribute to wave-resistance through submarine lithification; “non-framework reef builders” such as foraminifera, erect coralline algae (especially the genus *Halimeda*) and molluscs contribute greatly to reef sediments; “sediment

operators,” such as holothurians and burrowing worms and molluscs, aerate sediments and contribute to the productivity of sandy lagoons; “facilitators” such as herbivorous fishes and invertebrates keep algal biomass in check that might otherwise limit coral settlement and survival.

Resilience in biota and functional roles is as much dependent on the existence of the wave-resistant structure as it is a contributor to it. A critical third pre-requisite is a hydrodynamic setting that acts to retain the reef debris within the existing reef footprint. Reefs with this combination of resilient populations of corals, other reef builders and facilitators, high carbonate production, and strong retention have been termed “production-dominated” (Kleypas et al., 2001). These authors note that a reef’s potential for this strongly autonomous growth may be limited in three ways: by a location and hydrodynamic setting that favors import and incorporation of exogenous sediments – marine or terrigenous (“import-dominated” reefs); export of reef-generated sediments (“export-dominated”); or such a poor larval supply and/or conditions for coral growth that it cannot keep up with losses caused by bioerosion (“bioerosion dominated”). This latter style is classically represented in back reef areas that become isolated from the ocean by the coral reef’s own profligate growth (Macintyre, 2007).

“Coral communities” (*sensu* Buddemeier and Hopley, 1988; i.e., those that do not advance beyond stage “a” in Figure 1) are extreme examples of an “export-dominated” setting. These corals settle directly on “non-reefal” substratum, and on their death, are physically and biologically eroded down to silt, or fall off (precluding framework accretion and sedimentary infilling), and are carried by currents and gravity into places too deep, too turbulent or too sandy for additional coral settlement or survival.

“Incipient reefs” (a term preferable to “coral reef communities”; Figure 2b) are coral reefs in the making. They have had insufficient time to complete sufficient incremental vertical growth and “stepping out” to be considered a “coral reef.”

## Summary

Two similar definitions (“coral reef” and coral-algal reef) are provided, one strictly geological and one that specifies *living* corals as a fundamental defining characteristic of “coral reef.” The definition is then dissected, and allied terms such as “coral community” and “coral reef community” discussed, noting the completely different meaning of these terms in geology and ecology. The importance of ecological processes in keeping up the supply of building blocks (corals and reef debris) is discussed. Differences in local environment and in particular, hydrodynamic setting, lead to different intergenerational performance of coral populations, and also the propensity for reefs to act as sediment importers, producers or exporters, or to be in a state of net loss due to bio-erosion. A place’s environmental regime considered over decadal time scales and up (including “normal” conditions and extreme

events) will determine the likelihood of a coral community making the transition (Figure 1) to an “incipient coral reef” (early stages of development of a wave resistant structure) and a “coral reef” proper. Key determinants are first, whether there is a sufficient density of corals in a sufficiently large area that grow long enough and get large enough to create a wave-resistant structure; and second, whether that structure gets large enough to attenuate and refract waves and currents in a manner that promotes the retention and compaction of its own biogenic sediments within and around itself.

Just as the terms “juvenile,” “mature,” and “senescent” are applied to the coral reefs as geological structures, so are they applied to the tracts of corals for which the structure is simply “substratum.” However, the links between coral dynamics and reef development are poorly understood (Perry et al., 2008b). Improved understanding is important, especially in light of serious, persistent, and widespread declines in coral cover and resilience (e.g., Bellwood et al., 2004) and some very bleak projections for the future of coral reefs under global climate change (Veron, 2008).

## CORAL REEFS OF INDIA

Krishnamoorthy Venkataraman  
 Marine Biology Regional Centre, Chennai, India

### Definition and introduction

Coral reefs are one of the most ancient and dynamic ecosystems of India. Coral reefs not only provide a sanctuary to a myriad of marine life but also play a key role in protecting the coastline from erosion. In addition, people living along the 8,000 km long coastal stretch of India depend on coral reefs for their livelihood (Venkataraman and Alfred, 1998, Venkataraman, 2003). India is centrally placed within the warm tropical region of the Indian Ocean and exhibits extensive coral reefs in its marine territories. In India, major coral reef ecosystems are seen in Gulf of Mannar, Gulf of Kachchh, Andaman & Nicobar, and Lakshadweep Islands, which embrace all the three major reef types (atoll, fringing, and barrier) and include diverse and extensive reef areas of the Indian Ocean (Figure 1). Fringing reefs are found in the Gulf of Mannar and Palk Bay. Platform reefs are present along the Gulf of Kachchh. Patch reefs are present near Ratnagiri, Malvan, and Kerala coasts. Fringing and barrier reefs are found in Andaman and Nicobar Islands. Atoll reefs are found in Lakshadweep. Absence of reefs in the Bay of Bengal along the northeast coast is attributed to the immense quantity of freshwater and silt brought by the rivers such as Ganga, Krishna, and Godavari. The total area of coral reefs in India is estimated to be 2,375 sq km.

The studies on the taxonomy of Indian coral reef started as early as 1847 by Rink in Nicobar Islands, and later in 1898, Thurston worked on coral reefs in Gulf of Mannar region. During the whole of twentieth century, many foreigners contributed to coral reef studies in India. Pillai (1983, 1986), the first Indian worker, published many papers on the coral diversity from all the four major coral reefs of India followed by Venkataraman (2003, 2006), Venkataraman and Alfred (1998), and Venkataraman et al. (2003).

**Coral Reefs of India, Figure 1** Major coral reef areas in India.

## Coral reefs: East Coast of India

### Gulf of Mannar

The Gulf of Mannar reefs are found around a chain of 21 islands that lie along the 140 km stretch between Tuticorin and Rameswaram. These islands are located between latitude  $8^{\circ} 47'N$  and  $9^{\circ} 15'N$  and longitude  $78^{\circ} 12'E$  and  $79^{\circ} 14'E$ . The islands lie at an average distance of 8 km from the main-land. They are part of the Mannar Barrier reef, which is 140 km long and 25 km wide between Pamban and Tuticorin. Different types of reef forms such as shore, platform, patch, and fringing type are observed in the Gulf of Mannar (Venkataraman et al., 2003). The islands have fringing coral reefs and patch reefs around them. Narrow fringing reefs are located mostly at a distance of 50–100 m from the islands. On the other hand, patch reefs rise from depths of 2–9 m and extend to 1–2 km in length with width of as much as 50 m. Reef flat is extensive in almost all the reefs in the Gulf of Mannar. Reef vegetation is richly distributed on these reefs. Reef flat and reef vegetation including algae occupies 65 and 14 sq km, respectively (D.O.D and S.A.C., 1997). Pillai (1986) had provided a comprehensive account of the coral fauna of

this region. There are about 94 species of corals belonging to 32 genera in the Gulf of Mannar. The most commonly occurring genera of corals are *Acropora*, *Montipora*, and *Porites*. Extensive sea grass beds are present; green turtles, olive ridley turtles, and dugongs are dependent on these sea grasses as their feeding ground.

### Andaman and Nicobar Islands

The Andaman and Nicobar group of Islands is located in the South East of the Bay of Bengal, between  $6^{\circ}$ – $14^{\circ}N$  latitude and  $91^{\circ}$ – $94^{\circ}E$  longitude. They are the emerged part of a plate edge mountain chain and lie on a ridge that extends southward from the Irrawaddy delta area of Burma, continuing the trend of the Arakan Yoma range.

The Andaman and Nicobar group of islands consist of 530 islands, of which only 38 are inhabited, along with a number of exposed islets and rocks. The principal of these is the North Andaman, Middle Andaman with Ritchies archipelago in the east, South Andaman, little Andaman, Baratang, and Rutland Island. The coral reefs are of fringing type and except for a few investigation reports, the reefs of the area still largely remain unknown.

A deep oceanic ridge along 10°N separates the Andaman Group and the Nicobar group of islands. The orientation of the chain of islands is north-south. In these island groups, there are two Marine National Parks viz., Mahatma Gandhi and Rani Jhansi Marine National Parks. The coral fauna is diverse when compared to other parts of India (Turner et al., 2001).

### West Coast of India

The West Coast of India between Mumbai and Goa is reported to have submerged banks with isolated coral formations (Nair and Qasim, 1978). Coral patches have been recorded in the intertidal regions of Ratnagiri, Malvan and Rede, south of Mumbai (Qasim and Wafer, 1979), and the Gaveshani bank, 100 km west to Mangalore (Nair and Qasim, 1978).

### Malvan

The Malvan coast forms part of the Western Ghats where the Sahyadri ranges gradually meet the Arabian Sea. From Vengurla point, the coast tends towards the north for about 22 km. From Malvan bay, a chain of submerged and exposed rocky islands extends directly south to 15°53'N and 73°27'E. In this chain, several islands exist including Vengurla Rocks at the Southern tip and Sindhudurg Fort at the northern tip. Other small islets around Sindhudurg Fort are Mandel Rock, Malvan Rock, etc. Most of the marine flora and fauna in the intertidal area are exposed during low tide. However, during lowest low tides (particularly negative tides), the coral reefs get exposed. *Porites*, *Coscinaraea*, *Turbinaria*, *Favia*, and *Pseudosiderastrea* are some of the genera reported from this coast (Venkataraman et al., 2003). Siltation is high and salinity may drop to 20 ppt during the monsoons in some habitats, which may restrict the growth of ecologically sensitive forms of ramose corals.

### Lakshadweep Islands

The Lakshadweep Islands lie scattered in the Arabian Sea at about 225 – 450 km from the Kerala coast. Geographically, the islands lie between 8°N–12°3'N latitude and 71°E – 74°E longitude. The islands consist of coral formations built up on the Laccadive-Chagos submarine ridge rising steeply from a depth of about 1,500 to 4,000 m off the west coast of India. The Union Territory of Lakshadweep along with the Maldives and the Chagos Archipelagoes form an interrupted chain of coral atolls and reefs on a continuous submarine bank covering a distance of over 2,000 km. This ridge is supposed to be a continuation of the Aravali Mountain, and the islands are believed to be remnants of the submerged mountain cliffs. There are six tiny islands, 12 atolls, 3 reefs and 5 submerged banks, covering an area of 32 km<sup>2</sup> with lagoons occupying about 4,200 km<sup>2</sup>. Only 11 of the 36 islands are inhabited. Minicoy Island is separated from the rest of the islands by a 180 km wide stretch of sea known as the Nine-degree Channel.

The coral fauna of Lakshadweep is known to harbor 105 species belonging to 37 genera (Pillai, 1996). *Acropora* spp., *Pocillopora* spp., *Porites* spp., and massive and encrusting favids dominate the lagoon and reef flat faunal elements. *Psammocora* spp. are common in the northern islands. There is an abundance of blue coral *Heliopora coerulea*. *Millepora* spp. is dominant in the lagoon. Minicoy has species such as *Lobophyllia* and *Diploastrea* that are common to the Maldives but rarely found in the northern islands. Similarly, the genera *Montipora* and *Echinopora* recorded from the northern group of atolls are not recorded in Minicoy.

### Gulf of Kachchh

Gujarat State has a 600 km long coastline, which is very rich in various edible fishes and various types of algae. The Gulf of Kachchh is the richest source of floral, faunal and marine wealth of India, as it provides favorable conditions for breeding and shelter to all marine life in the 42 islands. The corals in the Gulf of Kachchh survive through extreme environmental conditions such as high temperature, salinity changes, and high-suspended particulate loads. Gulf of Kachchh Marine National Park and Sanctuary is the first National Park in the country (457.92 sq km). The Gulf of Kachchh has the best developed coral reefs along the western coast. Out of the 42 islands in the Gulf, 34 islands are surrounded by fringing or platform reefs. Out of 37 hard coral species reported earlier, only 36 are currently found.

### Geology and geomorphology of Indian coral reefs

Coral reefs characterize an ecosystem of high biological diversity, having the greatest number of species of any marine ecosystem. Coral reefs act as a barrier against wave action along coastal areas thus preventing coastal erosion as well as protecting mangroves and seagrass beds in certain areas, which are the breeding and nursing grounds of various economically important fauna (Venkataraman and Alfred, 1998). However, the processes of erosion, sedimentation, periodic storms, flooding, and sea level change, continually modify the ecosystem. The Holocene transgression, the latest episode of sea-level fluctuations, has left behind many signatures which provide insight into the nature of these changes. Direct and indirect palaeo sea-level indicators (see: [Sea Level Indicators](#)) have been identified with transgressive, regressive or still-stand conditions. These include specific biological indices of corals, molluscs, foraminifers, etc., and certain geomorphological features such as submarine terraces, reefs, notches, raised marine deposits, beach rocks, buried channels, etc (Vora et al., 1996). Glacio-eustatic sea-level fluctuations, along with relief, lithology, sedimentation, tectonic movements, etc., produce depositional and erosional patterns which govern the topography of the continental shelf of the Andaman and Nicobar Islands and other coral reef areas of India (Bruckner, 1988). The topography of the continental shelves where major coral reefs of India are found

(Gulf of Kachchh, Gulf of Mannar, Lakshadweep, and Andaman and Nicobar Islands) is mainly governed by depositional and erosional processes, which occur during glacio-eustatic sea level fluctuations. Other factors involved, directly or indirectly, are structure, lithology, sedimentation, tectonic movements, and climatic changes.

Seismic data from the west coast of India revealed the occurrence of buried reefs off Saurashtra and Ratnagiri, indicating pinnacles and protuberances of different heights. The cliffy coast of southern Saurashtra has preserved a record of the sea level changes during the late Quaternary (Rao and Wagle, 1997). Based on the geomorphic positions of the notches, the older sea strand lies at an elevation ranging from 12 to 15 m above the present BMSL and has been attributed to the last interglacial (MIS-5). Following this, a major tectonic uplift of about 6–9 m was experienced by the southern cliffed coast. The Holocene sea level was recorded at 4–5 m which is about 2 m higher than the general MIS-1 sea level. Thus, the submarine terraces on the shelf must have also been formed during the late Pleistocene to mid-Holocene still stands of the sea level. Radiocarbon dates of surficial samples of algal, oolitic, and coralline limestone (Nair and Hashimi, 1980) collected from the terraces and/or in their vicinity suggest that the innermost terrace along the shelf (55–60 m) is ca 7,845 yrs B.P., and the outermost terrace on the shelf is ca 11,150 yrs B.P.

The distribution of reefs on the west coast shelf is random which perhaps may imply that conditions for reef growth have not been uniform. It is interesting to note that between Mumbai and Mormugao, where the shelf is relatively broader, reefs occur abundantly on the middle and outer shelf. On the other hand, south of Mormugao, where the shelf is narrow, they are sparsely present and only on the outer shelf. Submerged coral reefs may be defined as reefs that were established in relation to a pre-existing sea-level lower than present and occur at depths greater than that commonly associated with vigorous growth of reef building, hermatypic corals. Further, the radiocarbon dating of coral and associated fauna indicates that they are of early Holocene age.

The Lakshadweep Islands rise from a submarine platform with coral reefs in the form of an atoll. It is crescent-shaped having a north-south orientation. The western margin of the lagoon is a submarine bank with a narrow reef below. The lithology is composed of an upper 1–2 m-thick layer of coral rubble, below which is a compact porous crust of conglomerate and soil composed mostly of coral sand. Topography is a flat 1–2 m above sea level. Erosion occurs mostly along the shore towards the northeast and northwest (Anon, 1990).

The Gulf of Mannar extends from Tuticorin to Rameswaram Island in a SW-NE direction and lies between 78°5' & 79°30'E longitudes and 8°47' & 9°15'N latitudes, a distance of about 140 km. There are 21 islands between Tuticorin and Rameswaram. All islands are composed of a calcareous framework of dead reef and sand and have a low and narrow sandy coast.

Around all offshore islands, well-developed coral reefs occur. Geomorphologically, coral reefs in this area are of fringing type, though some patchy corals are also observed in between Appa Island and Pilliyarmuni Island, and in some areas such as the Bharathinagar coast and the southeast coast of Kariya Shuli Island (Loveson, 1993). Wave cut platforms are common on the coast of Mandapam, Ramaswami Madam, Pudumatam, Valinokkam, etc. Along the coast of the Gulf of Mannar, cliffs occur though at some places these features have been destroyed due to slumping. In the Gulf of Mannar, the slope and width of the continental shelf is approximately the same as the average for the eastern coast of India (Ahmed, 1972). The total width of the shelf is around 30 km having a slope of about 21'. The slope near the shore is about 4'. Recent depth contour maps indicate that the seafloor level decreases along the coast and around the islands due to emergence of the land or lowering of sea level (due to tectonism) and sediment deposition. The beach is gently sloping and marked with altered crests and troughs that are formed due to wave action. As the Gulf of Mannar is on the lee side of the northeast monsoon, there is no long-shore drift from the northeast that might affect the morphology of the spit, (Ahmed, 1972). The southwestern shore of Rameswaram has a tongue shaped spit.

The Andaman and Nicobar Islands are parallel to the arcuate plate boundary separating the Indian and Sunda Plates east of the 9°E ridge (Dasgupta and Mukhopadhyaya, 1993; Rajendran and Gupta, 1989). The ridge is believed to have been formed from sediments scraped off the descending Indian Plate interleaved with ophiolites from the ocean floor beneath the Bengal Fan. In that, the islands are bounded to the east by strike-slip faults and spreading centers, and to the west by a subduction zone, the Andaman and Nicobar ridge acts as a small tectonic plate that has been referred to as the Burma Plate by Curray et al. (1982) and as the Andaman Plate by Dasgupta (1993). The geology of the Andamans is described by Oldham (1884) and Tipper (1911).

A series of earthquakes ranging up to a magnitude of 7.5 under the Andaman and Nicobar Islands on 26 December 2004 shook the entire Andaman Sea region. The end result was that the Burma Plate, which contains the Islands, tilted during an earthquake "swarm" lasting for about 8 min after the major quake off Sumatra. Thus, these islands were a source of the tsunamis that spread out across the Indian Ocean and themselves impacted by tsunamis from the whole series of plate movements on that morning. The effects were very different on the mainland of India to the offshore Andaman and Nicobar Islands.

The primary slip offshore of Sumatra was followed by two other slips towards the north. Though some of these findings need to be further substantiated, the fact remains that the Sumatra earthquake caused significant changes to the earth's tectonic processes (Ortiz and Bilham, 2003). The Andaman and Nicobar area, including Car Nicobar, Katchel, and Campbell Islands were not only affected by

the earthquake but also by the tsunami surge. A subsidence of 1–2 m affected the Nicobar Islands with the maximum down-throw at Indira Point near Great Nicobar. Out of the total area of the Nancowry group of islands, 15.64% of the area has undergone major changes. Nearly 6.8% of the area is submerged and 8.9% of area damaged. Maximum change (more than 42%) has been observed in Trinket Island. More than 23% of Katchall and 9% of Camorta and Nancowry and Tarasa groups have undergone major changes. This resulted in a rise in sea-level, inundating the coastal settlements and narrowing the beaches of the islands. Measurements made at Aerial Bay (Diglipur) and Rangat revealed retreat of sea level to the extent of 1.3 m at Campbell Bay, 1.0 m at Chhattam Island, 0.8–1.0 m in Aerial Bay and 0.4–0.6 m at Rangat. Land surveys at Diglipur and Mayabunder jetties (North Andaman) confirm a vertical uplift of the land up to 1.2 m from the pre-earthquake levels; exposed piles of the jetties, coral reefs and the receded waterline at these jetties stand as testimony to this change (Figure 3).

The coral reefs of Andaman and Nicobar Islands have been damaged by the impact of the recent tsunami and physical removal of other coral reef associated flora and fauna. The tsunami waves increased the sediment load which has smothered and killed sediment sensitive corals and sea grasses. There is significant contamination of coral reefs and coastal waters by run-off from the land, with large quantities of waste and pollutants, debris, soil, and organic matter. Nesting beaches for the five species of globally threatened marine turtles in the Andaman and Nicobar Islands and on the east coast of India have also been damaged.

### Coral reef associated biodiversity

#### Scleractinian corals

Pillai (1983) recorded a total of 199 species divided among 37 genera, from India, which includes Lakshadweep (78 species), the Gulf of Kachchh (37 species), Palk Bay and the Gulf of Mannar (94 species) and Andaman and Nicobar Islands (135 species) (Figure 2). This account

Coral Reefs of India, Figure 2 Diversity Scleractinia in the major coral reef areas in India.

**Coral Reefs of India, Figure 3** The exposed coral reef in the Landfall Island, North Andaman.

includes both hermatypic and ahermatypic corals from the four major coral reefs of India. Venkataraman et al. (2003) identified 15 families, 60 genera and 208 species of Scleractinia (reef building and hermatypic corals) from the four major reefal areas of India such as Gulf of Kachchh (36 species), Lakshadweep (91 species), Gulf of Mannar and Palk Bay (82 species), and Andaman and Nicobar Islands (177 species).

The diversity of scleractinian corals in Gulf of Kachchh is very poor when compared to all the other three major regions of India. Families such as Asterozoeniidae, Pocilloporidae, Euphyllidae, Oculinidae, Agariciidae, Fungiidae, and Trachyphylliidae are totally absent. Species such as *Siderastrea savignayana* and *Acanthastrea hillae* are reported only from Gulf of Kachchh. Twelve families, 34 genera and 91 species are reported from the Lakshadweep Islands. Families such as Asterozoeniidae, Pectiniidae, and Trachyphylliidae are absent. Among the 60 genera recorded in India, only 34 are reported so far from Lakshadweep. Thirteen families, 27 genera and 82 species are reported from the Gulf of Mannar and Palk Bay. From the Andaman and Nicobar Islands, 15 families, 57 genera, 177 species are reported. All the fifteen families reported from India are represented in these islands.

### Algae

Marine algae or seaweeds form an important reef resource in India. A recent publication on the compilation of all the new records of marine algae of India shows that benthic marine algal flora of Indian coasts comprises 844 species under 217 genera including forms and varieties (Oza and Zaidi, 2000). Out of these, the maximum number have been recorded from the Gulf of Mannar (302), followed by 202 species from the Gulf of Kachchh, 159 species from the Malvan coast, 89 species from the Lakshadweep group of Islands and 82 from Goa. In India, seaweeds are exploited and used as raw materials for the production of agar, alginates and seaweed liquid fertilizer. Data on seaweed landings in Tamil Nadu from 1978 to 2000 reveal

that the quantity (dry wt) extracted in a year during this period varied from 102 to 541 t for *Gelidiella acerosa*, 108–982 t for *Gracilaria edulis*, 2–96 t from *G. crassa*, 3–110 t for *G. foliifera*, and 129–830 t for *G. verrucosa* (Ramalingam, 2000).

### Sea grass

Indian coral reefs embrace only 6 genera and 14 species of sea grasses. Distribution of sea grasses along the Indian coast varies with varying species diversity viz. Gulf of Mannar 13 species, Gulf of Kachchh and Lakshadweep 7 species and Andaman and Nicobar reefs 9 species (Kannan et al., 1999). All the 6 genera of sea grasses with 11 species are recorded from the Palk bay region. Of the 11 species, *C. serrulata*, *H. ovalis ovalis*, *K. pinifolia*, and *S. isoetifolium* are the most widely distributed. Out of the 14 species of sea grasses, nine species occur in the Andaman and Nicobar Islands.

### Other marine fauna

Other marine fauna illustrate the great diversity of India's coral reef biota. Some 451 species of sponges from 169 genera have been recorded (Pattanayak and Buddhadeb, 2001). Dominated by Desmospongia, greatest diversity is found in the Gulf of Mannar and Palk Bay. Four turtle species (leather back, Hawksbill, green and Olive ridley) have been observed nesting in the Andaman and Nicobar Islands, (Basker, 1984). Dolphins are common in many areas and dugong in areas of sea grass. More than 1,000 coral reef fish species are found with greatest diversity in the Andaman and Nicobar Islands. There are 3,570 species of marine molluscs (Subba Rao, 1998), almost 3,000 species of Crustacea (Venkataraman and Krishnamoorthy, 1998) and 765 species of echinoderms, 257 in the Andaman and Nicobar Islands alone (James, 1987).

### Threats to coral reefs

Coral reef resources have traditionally been a major source of food for local inhabitants and of major economic value in terms of commercial exploitation. The human exploitation of marine resources has increased dramatically over the last few decades for both reasons of commercial and subsistence living. Coral reef ecosystems of India have been exploited for a very long time, but it is only in the last century that the rate of exploitation has increased dramatically due to the increase in the human population. Except for some of the Andaman-Nicobar Islands, no pristine area exists today.

Varied human activities which are a cause for concern over and above the natural disturbances include, runoff and sedimentation from developmental activities (projects), eutrophication from sewage and agriculture, physical impact of maritime activities, dredging, collecting, and destructive fishing practices, pollution from industrial

sources and oil refineries and the synergistic impacts of anthropogenic disturbance.

Fishing is a major activity, and at present in the 3,651 fishing villages situated along the 8,129 km coastline of India, about one million are occupied in full time marine capture fisheries. The value of the annual marine fish production of 4.6 m t during the year 2002–2003 and the value of marine products export were US \$152.92 m. This is mainly due to the introduction of bottom trawlers, into Indian waters in the early 1960s. Several types of net fishing have also been responsible for the over-exploitation of marine resource. Along with increase in the targeted catch, a number of untargeted fish and other biota are removed from their habitat and discarded as waste (trash fish). Shrimp trawlers probably have the highest rate of by catch bringing in up to 90% more of “trash fish”. A total of 1,006 purse seines in India employed for fishing may have the same effect on the seabed as that of the trawl netting. Random capture techniques employed in India destroy immature fish and other non-targeted marine species. Gill nets used to catch fish bring in a host of other animals such as dolphins, turtles, *etc.* Because of the large size of the areas concerned (Gulf of Mannar and Andaman and Nicobar Islands or other areas in India), and the general lack of resources for enforcement, awareness education appears to be more successful than legislation in controlling these activities.

Although now illegal, blast fishing has been a widespread fishing technique in India. Schooling reef fishes are located visually, after which the capture boat moves within close range and a lighted bomb is thrown into the middle of the school. Due to blasting, branching, tabulate and foliose hard corals are shattered while massive and columnar corals are often fractured. Bombs made of chemical fertilizers such as ammonium/potassium nitrate were confiscated from the foreign poachers apprehended in Andaman and Nicobar Islands. Gelatin sticks were observed to be used to blast fish by the fishermen around Gulf of Mannar reefs (Venkataraman et al., 2003).

Sedimentation throughout the coast of India physically interferes with the recruitment of coral larvae, which require a solid substratum upon which to settle and metamorphose. Illegal sand mining in Andaman Islands and illegal coral quarrying in Gulf of Mannar (Tuticorin group of Islands) and some islands of Gulf of Kachchh have caused a lot of sedimentation and siltation on coral reefs.

There has been unprecedented bleaching of hard and soft corals throughout the coral reefs of the world from mid 1997 to late 1998 (Wilkinson, 1998, 2000). Most of the corals in the coral reefs of India have been adversely affected during the bleaching in 1998, which destroyed most shallow water corals. This event has greatly reduced live coral cover in the reef (Venkataraman, 2000). Study conducted after or during the bleaching event reported a reduction in live cover of corals in Gulf of Kachchh (20–40%), Gulf of Mannar (20–40%), Lakshadweep (20–30%) and Andaman and Nicobar Islands (<10%).

The live coral cover in Andaman and Nicobar Islands was between 50–75%, which is very high when compared to other reefs in the Indo-Pacific region (Muley et al., 2000, Rajasurya et al., 2002).

In addition to natural and human induced coral degradation, coral diseases are considered to be one of the major problems faced by the coral reefs in recent years. Necrotic lesions, fleshy algal over-growth, black band disease, and white band disease have been reported from the Andaman and Nicobar and Lakshadweep Islands. In addition, a new disease called pink line disease has also been reported recently from Lakshadweep (Ravindran and Raghukumar, 2006).

The coral eating starfish, *Acanthaster planci* was the focus in the late 1980's and early 1990's in the Andaman and Nicobar Islands as well as in other coral reef areas of India (Venkataraman and Rajan, 1995). Although sediment core data have indicated *Acanthaster* outbreaks 10,000 years ago, recent studies have shown a relationship between nutrient input and recruitment success of the larvae. Studies on echinoderm reproduction have demonstrated that the success of the recruitment of their planktonic larvae depends on phytoplankton availability following spawning.

#### Coral damage from the Tsunami of 26th December, 2004

The major damage to reefs is caused by storms, particularly tropical cyclones and by tsunami. These cause major intermittent damage to reefs, particularly to those reefs that rarely experience these storms. Due to a 1969 cyclone, a large area of coral was buried under sand in the Rameswaram area of the Gulf of Mannar. Likewise, the cyclone of December 1987 in the Bay of Bengal devastated the coral reefs of the Mahatma Gandhi Marine National Park of Port Blair, Andaman that resulted in piles of broken coral colonies scattered near the shore.

A very severe earthquake with a magnitude of 9.0 on Richter scale struck northern Sumatra, Indonesia on 26th December, 2004, and it was widely felt along the east coast of India. In Tamil Nadu, people felt distinct tremors in many parts of Chennai. The quake was also felt along the Coromandel Coast up to some areas in Vizakapatnam. The devastating tidal waves consequent to the earthquake lashed several coastal districts of Tamil Nadu and Puducherry as well as the archipelagos of the Andaman and Nicobar Islands. The Nicobar Islands were most severely hit given their proximity to the island of Sumatra and the epicenter of the earthquake. It is reported that shallow water coral reefs in the Andaman Islands have been exposed 2 m above the water mark (Figure 3) whereas the Nicobar group are submerged 2.0 m below the water mark (Venkataraman, 2006).

#### Conservation

India has 36 marine protected areas of which 20 are entirely located in intertidal/subtidal or seawater-mangroves, coral

reefs, lagoons, estuaries, beaches, etc., and 13 having major parts in marine ecosystem and some part in terrestrial ecosystem (Singh, 2002). The Wildlife Protection Act, 1972 provides protection for these areas and certain marine species. Corals are protected under this act. India's Coastal Regulation Zone Notification (1991) regulates onshore development activities, which affect coastal environments. Coral reef conservation is also included in the Environmental Protection Act (1986), the National Conservation Strategy and Policy Statement on Environmental Development (1992) and the Action Plan of the Ministry of Environment and Forests.

## Conclusion

Coral reefs in India have drawn great attention from the eighteenth century onwards. This was achieved from many surveys and expeditions conducted by foreigners, in particular by the British. The introduction of Surgeon Naturalists in the expedition ships helped marine research to flourish in varied fields of fauna and flora. However, in India, major studies have been conducted only on the commercially important organisms such as crustaceans, molluscs, holothurians, and higher vertebrates. Many minor phyla which are not commercially important have not been studied so far. For example, species of different minor phyla that live as the interstitial fauna of coral reef areas have not been studied till date, due to a lack of expertise in this field. Though taxonomy is being taught as a subject in the curricula of schools and colleges, there is no committed institution for the learning of taxonomy except survey departments under the placard of the Government of India. Probably, more than 75% of the biodiversity of coral reefs of the Andaman and Nicobar and Lakshadweep is not yet studied. This is mainly attributed not only to the decline in the number of taxonomists but also due to the lack of facilities. Geological and geomorphological studies are probably even less advanced which is unfortunate given the wide geographical distribution of coral reefs in India.

## CORALS: BIOLOGY, SKELETAL DEPOSITION, AND REEF-BUILDING

John E. N. Veron  
 Oak Valley, Australia

### Definition

Scleractinian corals (Phylum Coelenterata, Class Anthozoa, Order Scleractinia – the true stony corals alive today) have been building coral reefs for 250 million years, reefs that are the biggest structures ever made by living organisms.

### Introduction

Scleractinian corals have a simple structure. Their bodies are sac-like polyps that usually grow together to form colonies. They have a body wall with only two cell layers and a skeleton made of calcium carbonate which is actually outside their body so that the living polyp grows on its skeleton (Figure 1). This simple structure allows most corals to form complex colonies that are readily modified to suit a wide range of environments. Modern coral reefs are principally made of calcium carbonate that has been derived from coral skeletons and cemented into a wave-resistant structure by coralline algae (see [Coral Reef, Definition](#)). Whereas coralline algae generally have a wider distribution range than corals, both flourish in shallow, turbulent, well-lit environments, which is where highly consolidated reefs best grow. Growth rates of coral colonies and of reefs are very different and are discussed below: coral growth rate is a result of each colony's individual physiological performance within its particular environmental setting and reef growth is a net outcome of history, hydrodynamics, ecosystem processes, and the functional roles of various guilds of species – both constructive and destructive. Moreover, there is wide diversity of entities referred to as “reef,” with the contribution of corals likewise varying in importance: these are reviewed briefly here.

### Reefs and coral reefs

The term “reef” can mean different things to different people. To most geologists and palaeontologists, reefs are rock formations. To most biologists, reefs are a veneer of living organisms forming an ecosystem, which is both complex and fragile. These two concepts of reefs can seem as remote from each other as forests are from coal deposits, yet they share a common past. Reefs, the geological structures, are the direct products of living ecosystems and as such their formation has always been controlled by the sorts of events that control other ecosystems, both marine and terrestrial.

When considering ancient reefs, it is important to distinguish these “reefs” from the “coral reefs” of today. Corals are not the main builders of all reefs: many ancient reefs, especially those of the Palaeozoic, were not built just by corals but by a wide array of other taxa including

**Corals: Biology, Skeletal Deposition, and Reef-Building, Figure 1** The general structure of a coral polyp and underlying coral skeleton (After Veron, 2000).

algae, sponges, and molluscs. In many Palaeozoic reefs, sponges rather than corals were the dominant builders and in some late Mesozoic reefs, the same role was played by molluscs (rudist bivalves).

Even modern reefs are not necessarily coral dominated. Some, forming intertidal structures in the Caribbean and Bermuda, are made by vermetid “worms” (molluscs). There are also widespread subtidal structures dominated

by serpulid worms (annelids) and odd reefs everywhere owe their existence to other organisms, especially oysters. However, in terms of quantity, the reefs dominated by organisms other than scleractinian corals and their allies (including a few small taxa such as the blue coral *Heliopora* and the fire coral *Millepora*) are insignificant and have little in common with coral reefs other than in the material of which they are made. Such structures

excluded, the term “coral reef” still needs constraining, for some deep ocean corals form extensive structures, built by one type of coral (*Lophelia*). These are commonly called reefs, but they have none of the characteristics of coral reefs as geological structures (they do not form solid limestone) or as biological structures (they do not depend on photosynthesis nor are they biologically diverse).

There is one further distinguishing characteristic of coral reefs: although they are principally made of calcium carbonate derived from coral, coral skeletons need to be cemented into solid rock by coralline algae. Coralline algae generally have a wider distribution range than corals, but those that cement coral debris into reefs flourish in shallow, turbulent, well-lit environments and thus it is they as much as corals that determine where highly consolidated reefs best grow. They may also have a dominant influence on how fast they grow or if they grow at all in deeper water.

### Reef carbonates

Although most (90–95%) of terrestrial limestone is derived from reefs built by a variety of animals in shallow marine environments, this by no means reflects the principal source of carbonates on Earth. Around 90% of all today’s marine carbonates are deep-sea sediments derived primarily from plankton (mostly foraminifera and coccolithophores). Due to their deep water location, these are rarely uplifted to form geological rock formations on land; rather they are either dissolved in the ocean or subducted into the Earth’s mantle. Another 5% of carbonates are of mixed composition and are found on continental slopes. In a few regions, these carbonates have been consolidated and uplifted or otherwise exposed on land.

Perhaps surprisingly, only 5% of all carbonates today are of coral reef origin although this small proportion includes vast tracts of mountain slopes like the calcareous reefs of Austria. The proportion of total carbonates which are represented by living reefs is much less than 1%. Nevertheless, this small proportion is all important.

### Reef building

If corals grow in sufficient quantity, and the rate of both skeleton production (calcification) and algal cementation exceeds that of erosion, the resulting accumulation of calcium carbonate can form limestone reefs. The success of the process depends on speed, which is why reef-building corals enlist symbiotic algae (zooxanthellae, [Figure 2](#)) to harness the energy of the sun to power the process. This begs the question, why do these organisms put so much metabolic effort into reef-building? After all, no other ecosystem in all Earth’s history puts anything like as much energy, or such evolutionary focus, into building anything that is dead.

One answer lies in the purpose of skeleton building. Only corals that build reefs have large, three-dimensional, wave-resistant skeletons. This capacity has been achieved by removing the limitations of individuals and replacing

### Corals: Biology, Skeletal Deposition, and Reef-Building,

**Figure 2** An electron microscope image of a zooxanthella. This tiny cell, 10  $\mu\text{m}$  in diameter, has all the structural components of a typical algal cell (Electron microscope image: Ove Hoegh-Guldberg).

them with a wider range of options offered by the formation of colonies (groups of individuals formed asexually and which grow in unison). The implication is that skeletons are needed to form colonies and that colonies are needed to build large wave-resistant structures.

The two evolutionary innovations of colony formation and algal symbiosis clearly go together and have very likely evolved together. The importance of this is demonstrated by the fact that most Cnidaria involved in reef-building are both colonial and symbiotic. The two major groups of extinct reef-building corals (rugose and tabulate corals) are also colonial; however, it is not known if they were also symbiotic.

Coral reefs are ecosystems, which mean that they are not just aggregations of individual species competing with each other for survival, but rather groups of species living cooperatively for joint survival. Certainly individual species compete; however, a level of selection takes place which is higher than the selection of species. From a Darwinian perspective, this might be called “selection for survival of the fittest ecosystem” as opposed to selection for the fittest species. Where there is a close symbiosis between two species, the evolutionary success of one species is dependent on that of the other: natural selection acts on the partnership, not the species. A coral reef has hundreds of such interdependencies, resulting in a complex coevolution of subcomponents and entire ecosystems.

This introduces the concept of guilds (Bellwood et al., 2004), where each guild is a functional unit whose task is undertaken by a group of species or individuals. All coral reefs have many guilds including corals (to produce building blocks), coralline algae (to cement the blocks together), herbivores (to prevent macroalgae from taking over), and photosynthetic algae (to provide food). There

are also less prominent guilds, forming a hierarchy down to less conspicuous tasks such as parasite control, sediment mixing, and nutrient cycling. The essential point about guilds is that they are functional units selected for because they perform functions efficiently. It matters little what species perform the function, only that they do it with the necessary speed.

Corals are the most prominent reef-builders today because, with their zooxanthellae, they can harness the energy of sunlight to make building blocks sufficiently quickly to outstrip erosion. This is not to say that all zooxanthellate corals contribute to reef-building; perhaps half of all species make no significant contribution to reefs at all for they do not grow in environments suitable for reef growth, especially where the water is too turbid or too cold or where there is limited hard substrate, or because their skeletons are fragile and are easily removed by wave action.

The reason why corals build reefs has as much to do with the physical environment as with organisms: it is a matter of ecology.

### Light

Reef-building corals depend on photosynthesis for they use the unlimited resources of solar energy and air to produce food. However, about half of all Scleractinia (the azooxanthellate species) do not have symbiotic algae. Some azooxanthellate corals live on coral reefs, especially under overhangs or in caves, but with the exception of a few species that are both symbiotic and nonsymbiotic, all zooxanthellate corals need light, and it is only these taxa that build reefs. As a result, reefs are restricted to shallow sunlit waters. Azooxanthellate corals are not limited by light or by temperature, nor are they confined to shallow sunlit water; they live in the ocean depths where there is less competition for space. Therefore, they cannot build reefs and must live without food from photosynthesis: food can only come from detritus and the chance of capturing passing plankton.

### Algal symbiosis

Symbiosis, the interdependence of different organisms for the benefit of one or both participants, is much more prevalent in the oceans than on land. Within the spectrum of symbioses, zooxanthellae clearly have a special place. They are not just found in Scleractinia; they occur in other cnidarians (soft corals, anemones and their allies) as well as in an assortment of other animals including single-celled ciliated protists, sponges, flatworms, and molluscs (including giant clams). Once thought to be a single species, zooxanthellae have been found to be genetically diverse (consisting of many genetic types or “clades”) (Trench, 1979; Rowan and Powers, 1992), even though under a microscope they all look much the same (Figure 2). They can all live independently, although not in such concentrated numbers nor with such long-term security as they can live in the tissues of hosts. In the case of corals (but not clams), they live inside the cells of the

host organisms – in the innermost (gastrodermal) layer of the two cell layer body wall (illustrated above). All zooxanthellae are tiny, around one hundredth of a millimeter in diameter. Seldom does more than one occur in a single gastrodermal cell.

Zooxanthellae photosynthesize as do other green plants, releasing up to 95% of the nutrients they produce to the host organism (Muscatine, 1990). This is a curious arrangement because most corals are voracious feeders on zooplankton and therefore have two very different food sources. Nevertheless, many if not most corals that are kept in darkness (so that their zooxanthellae cannot photosynthesize) will start to die after a few months no matter how much food they have. Somehow, the zooxanthellae have made themselves indispensable. Just how or why remains unresolved.

In brief, important points about algal symbiosis are as follows (Hoegh-Guldberg, 1999 and many subsequent articles). Corals acquire their zooxanthellae either directly from the parent colony or through infection of free-swimming or newly settled larvae. Uptake of nonparental zooxanthellae in early life may be by random chance, giving different advantages to different colonies: some colonies might be infected with temperature-tolerant symbionts, others with more productive ones (this hypothesis has yet to be confirmed). Zooxanthellae readily change in abundance depending on conditions such as season, position on the coral, and light level. More than one genetic type of zooxanthellae can occupy a single colony. The abundance of genetic types varies geographically on any scale (Ulstrup and Van Oppen, 2003) and some genetic types facilitate a faster growth rate than others (Little et al., 2004).

### Water depth, turbidity, and latitude

Any factors which alter light in the marine environment will have a significant effect on calcification rates and reef development. Depth is a primary constraint as only a few zooxanthellate corals live below 100 m, even where the water is very clear and the substrate does not slope so steeply that it is shaded. *Leptoseris* commonly forms extensive beds to at least 160 m in the Red Sea and Hawaii, and there are several records of moderately diverse coral communities at depths of over 100 m elsewhere, including the outermost reef faces of the GBR.

Turbidity has a dominant role to play in controlling light levels in all except clear-water habitats. Where the water is not very clear, as is the case with most reefs near major land masses, coral diversity drops off sharply at depths below about 50 m. Where the water is particularly muddy, the depth limit for any coral can be as little as 5 m. Turbidity, especially that caused by fine clay particles which are easily resuspended by wave action, has other effects on corals besides reducing light.

Latitude also has an effect on light availability, much more in the ocean than on land due to the refraction of sunlight as it enters water. The higher the latitude the

shallower coral communities must be in order to have adequate light. This is of less consequence today than in past geological intervals when waters were warm enough for reef-building to occur at high latitudes, even as far as the Arctic and Antarctic circles.

### Temperature

Temperature, in synergy to some extent with light, sets limits on the latitudinal spread of corals throughout the world. A different temperature constrains the spread of reefs. The difference between these two – constraints on corals and on reefs – has created havoc in palaeoclimatic reconstructions of past reef environments as well as studies of reef growth because it is so widely misinterpreted.

#### Low-temperature limits to reef growth

It has been known for decades that reefs do not form where the ocean temperature regularly goes below 18°C for intervals of weeks to months. Reef geologists concerned with the history of reefs refer to this well-established fact, yet in so-doing they often assume that lower temperatures kill corals. This is seldom the case.

As noted above, reef-building allows entire ecosystems to exist, a process that can only happen if rampant growth of macroalgae is held in check (Crossland, 1988). This requires a great deal of uninterrupted energy, which is why reef-building corals are so dependent on symbiotic algae. We have also seen that this symbiosis requires exposure to sunlight, which means living in shallow water. Around 18°C corals are able to produce calcium carbonate fast enough to fulfil their guild role as producers of building materials. They are able to do this not by growing faster than algae, but by creating three-dimensional habitats where herbivores, especially fish, can control algae for them. At lower temperatures, algae usually get the upper hand; however, the corals themselves are not affected by temperatures lower than 18°C. This is best seen along the Ryukyu Islands of Japan where the southern islands have extensive reefs, yet further north the sea temperature progressively decreases until it reaches the critical 18°C point. It is here that reef development fails. The corals, however, do not: nearly half of all coral species regularly tolerate prolonged exposure to 14°C (Veron and Minchin, 1992). A few tolerate 12°C although seldom less (azooxanthellate corals excepted).

#### High-temperature limits to reef and coral growth

Low- and high-temperature limits do not mirror each other. Oceans can cool until they freeze, yet they cannot warm much beyond the peak temperatures we see today (around 31°C). This is because evaporation holds the upper limit in check, at least it does for extensive areas of ocean. Smaller bodies of water are less constrained, thus, reef lagoons can get at least 5°C warmer than this. Nevertheless, high temperature per se has little direct negative effect on corals. The warmer the water the faster most metabolic processes become and the faster calcification could become

if it were not for its effect on zooxanthellae. Faster metabolic rates for zooxanthellae mean faster photosynthesis, which in turn can result in oxygen being produced at rates where it becomes toxic. Corals are forced to expel their increasingly poisonous zooxanthellae and “bleach” in response to temperature and light acting in concert.

High-temperature limits of coral growth and reef growth are approximately the same as they are both linked to the upper limit of the ocean. This link is an evolutionary one and appears to have always existed for there is no interval in geological time where high temperature has excluded reefs from equatorial regions.

#### Substrate, turbulence, and mechanical effects

Substrate type and water clarity are always closely linked, especially when depth and turbulence are factored in. White calcareous sand, although typically coarse-grained, is light and therefore readily moved around by wave action, in which case it is capable of burying corals if suspended in sufficient quantity. However, it is clay from rivers that adversely affects corals, for not only does it attenuate light, but it also requires cleaning, a costly activity in terms of metabolic energy.

Substrate is also of paramount importance to settling larvae, for these will not settle on sand of any sort, or on substrates that are coated with bacterial slime, as it commonly develops on reefs that have been degraded.

One very obvious effect of turbulence on coral skeleton formation is that wave action produces dense skeletons. Corals in a high-energy environment grow dense skeletons, whereas those in protected areas have light, brittle skeletons. This is partly because of the differences in species that occupy these habitats, yet even within the same species this effect is pronounced.

#### Water quality

The term “water quality” is commonly used in connection with the health of the marine environment. Water quality that is good for particular coral reefs or coral communities is assumed to have tolerable levels of sediments and nutrients and environmental contaminants.

Salinity is an aspect of water quality that has not been adequately studied. Corals appear to be sufficiently tolerant of high salinity that lethal levels seldom, if ever, occur naturally. The opposite commonly applies to low salinities, for these play a large role in creating areas where there is little or no coral or reef growth.

There are other environmental controls on reef-building hidden in water chemistry that may not overtly limit reef distribution today but which may have been important in the geological past and are destined to become so in the near future. Oceans are normally so well buffered that chemical changes are infinitesimally slow, providing plenty of time for organisms to evolve adaptations to any alteration. However, sometimes the rate of change exceeds physical or biological thresholds and cannot be tolerated by any except the most specialised organisms. This can

happen when large tracts of ocean become anoxic, hydrogen sulphide concentrations become toxic, pH alters beyond tolerable limits for calcification, or other contaminants make the water uninhabitable.

### Rates of growth and erosion

Growth rates of coral colonies and of reefs are very different subjects because (1) reefs are made of a much denser material than are coral skeletons, (2) there are gaps between coral colonies that must be in-filled to make solid limestone and (3) reef accretion is the rate of growth minus the rate of erosion – the latter is commonly greater, especially in marginal habitats. This is the main reason why reefs do not form wherever coral grows.

### Coral growth rates

The much-studied coral *Porites* forms large hemispherical colonies which typically grow (radially) at a rate of around 1 cm per year as determined by X-rays of thin slices (Figure 3). Some more heavily calcified colonies of other corals grow at slower rates than this, although most are faster. Staghorn *Acropora* readily grows (linearly) up to about 30 cm per year. Plate-forming *Acropora* also grows (in diameter) up to about 30 cm per year.

### Reef growth rates

Rates of growth of reefs (accretion) can be measured directly from cores taken from reefs or by a wide range

of indirect measures of carbonate production (Vecsei, 2004). Normally, the maximum rate of reef growth is about 0.6 m per century (Smith, 1983), although rates in optimal conditions may reach three times this (Montaggioni, 2005; Hopley et al., 2007). These optimal conditions only occur where the water is shallow and clear and currents are strong, the probable reason why continuous areas of reefs (where there is more reef than open ocean) occur only where the tidal range is great and the ocean floor is shallow. These environments provide high light levels combined with continuous flushing and nutrient transport.

### Rates of reef erosion

There are no reliable estimates of rates of reef erosion because they are too slow to be directly measurable. Best estimates suggest that around 90% of all calcium carbonate produced by coral calcification is removed by erosion. There are four main mechanisms of reef erosion: physical erosion, enhanced chemical erosion, bioerosion, and rain-water dissolution.

1. Physical erosion leads to the formation of channels seen in most reefs due to the action of waves moving rubble back and forth. These channels typically develop into “spur and groove” structures common along most reef fronts exposed to strong wave action. On a bigger scale, erosion caused by tidal currents may produce “deltaic patterns,” so named because they resemble river deltas.
2. Changes in ocean chemistry which affect the stability of skeletal material can have a significant effect on the balance of reef accretion and erosion. Ocean acidification, predicted to occur during the present century, will bring this subject to the forefront.
3. Bioerosion is a greatly underrecognized process, yet can be very active in shallow water where it not only erodes the limestone surface but also prevents the growth of newly recruited corals and coralline algae on available substrates. Over thousands of years, the actions of many types of bioeroders, such as the urchins, would probably be capable of keeping pace with slow sea-level falls, or successions of slow falls, and therefore would leave no reef exposed above high tide level. There are many studies of the rate at which different organisms (such as sponges, urchins, limpets, chitons, and parrot fish) ingest limestone (typically up to 18 cm<sup>3</sup> per animal per year for intertidal invertebrates such as sea urchins); however, these cannot be reliably translated into rates at which these animals might plane-off whole reef surfaces.
4. Rainwater dissolution commonly results in “rill weathering,” a process that creates interlocking knife-like edges on the surface of limestone outcrops. Depending on the chemical composition of the limestone, some aerially exposed reefs last much longer than others, as evidenced by the ancient reefs that remain intact today.

**Corals: Biology, Skeletal Deposition, and Reef-Building, Figure 3** Growth bands in corals such as seen in this X-ray of a slice of *Porites* are the marine equivalent of growth rings in trees. They not only allow detailed measurements of growth rates, but can also reveal much about the environment in which the coral grew, including temperature and salinity (X-ray image: Janice Lough).

An important point about these forms of erosion are that the first three occur only when reefs are submerged, while the fourth occurs only when reefs are exposed to the air, either by uplift of the land or by falls in sea level.

## Summary

The subject of coral skeleton formation has two separate aspects, reef building and coral growth. Reefs are both geological structures and living ecosystems. Corals are often not the primary builders of Palaeozoic reefs, thus the terms “reefs” and “coral reefs” are not necessarily interchangeable terms in geological contexts. However, scleractinian corals are the builders of most Mesozoic and Cenozoic reefs. The environmental controls on both are similar, not necessarily the same.

The two great scleractinian innovations of colony formation and algal symbiosis allow corals to build reefs. These are closely linked, both functionally and in evolutionary terms. Light and temperature are the dominant parameters.

Light availability is critical for reef-building because of the dependence of corals on algal symbiosis. In turn, light availability is regulated by water depth, turbidity and (in geological time) latitude.

Temperature limits the latitudinal distribution of reefs and constrains the rate of skeleton formation. For ecological reasons, reef formations are limited to oceans that do not cool below 18°C for extended periods of time. However, most corals can grow where temperature commonly falls to 14°C. High-temperature limits to both reef growth and corals are similar, approximately 31°C.

Rates of coral and reef growth are very different. Rates of coral growth vary enormously according to the type of colony formation. Rates of reef growth are dependent on rates of erosion. This occurs by four processes, physical erosion, changes in water chemistry, bioerosion and rain-water dissolution.

## CORALS: ENVIRONMENTAL CONTROLS ON GROWTH

Terry Done  
 Australian Institute of Marine Science, Townsville, QLD,  
 Australia

## Definitions

**Coral growth:** The establishment, survival, and increase in size of living zooxanthellate corals as individuals, populations, and communities.

**Coral calcification:** The biological process of the synthesis of calcium carbonate by corals. Its rate is reported in  $\text{gm cm}^{-2} \text{ year}^{-1}$ . A given rate of calcification is manifest in a coral skeleton as its rate of linear extension ( $\text{cm year}^{-1}$ ) of a particular density ( $\text{gm cm}^{-3}$ ).

**Environment:** The physical, chemical, nutritional, and ecological milieu in which corals grow.

**Microenvironment:** “Environment” impinging upon an individual coral in situ.

## Introduction

Corals grow vigorously and build reefs in shallow tropical seas, due to the favorable environment, both “latitude-correlated environmental factors” (Veron, 1995) and factors that are not related to latitude. The latitude-correlated environmental factors are solar radiation, temperature, and water chemistry (Kleypas et al., 1999), and those not related to latitude include nature and depth of the substratum, wave climate, salinity, water clarity, nutritional properties of that water, and sedimentation regime. Collectively, they affect growth rate, growth form, reproduction and longevity of individual corals, the trajectories of abundance, size and age-frequency distribution and turnover rates of populations, and the composition and diversity of coral communities. These population and community attributes in turn influence the frequency and amounts of calcium carbonate skeletons that can be delivered to, and accumulate in, reef-building units (framework, boulders, blocks, rubble, and sand) – i.e., contribute to the growth of maintenance of a coral reef and adjacent sedimentary deposits against disaggregating forces of waves, currents, and gravity in shallow tropical seas.

Just as important as the normal fair-weather environment in determining a coral community’s extent and structure are the legacies of their history of development, disturbance, and recovery. Coral communities (see *Coral Reef, Definition*) are all works in progress – outcomes of the timing and makeup of successive settling cohorts of coral propagules (larvae and fragments) and a long list of species-specific differences among corals: their performance in competition with other benthic organisms trying to occupy the same piece of substratum (corals, other sessile invertebrates, and algae); attractiveness or resistance to predators and diseases; susceptibility to breakage or dislodgement by storms; propensity to collapse under their own top-heavy weight and fall off the reef into inhospitable depths; propensity to be dislodged, swept, rolled, or pushed from the area by waves and currents.

## Coral: the animal–plant symbiosis

Underpinning the coral vigor that builds reefs in tropical seas is the presence of hundreds of thousands of “zooxanthellae” (single-celled dinoflagellate algae in the genus *Symbiodinium*) within every square centimeter of the coral’s tissues (Fagoonee et al., 1999; Fitt et al., 2000). Corals that host zooxanthellae are referred to as “zooxanthellate” corals. Within its diurnally and seasonally variable external environment, the coral needs to provide an internal environment that nurtures the zooxanthellae. Whereas corals generally live for decades to centuries, the zooxanthellae populations and coral tissue in which they reside turn over on time scales of weeks to months (Fitt et al., 2000). Under extreme environmental stress, the coral’s internal environment can become inhospitable and zooxanthellae populations may crash and the coral tissue get damaged, leading to injury or death

of entire coral colonies across vast areas (see *Climate Change and Coral Reefs*).

Within coral’s favored environment, the symbiotic arrangement between the coral “host” and its zooxanthella “symbiont” provides such a hospitable intracellular environment for the symbionts that their photosynthesis produces a massive surplus of energy-rich compounds (Gattuso et al., 1999). These are used by the coral polyps to fuel their replication and to deposit their shared skeleton. The rate of calcification (see Definition above) in zooxanthellate corals far exceeds that which is possible in cnidarians that lack zooxanthellae: their presence drives “light-enhanced” calcification (Goreau and Goreau, 1959). However, one decade into the twenty-first century, the coral–zooxanthellae symbiosis, in existence since the Tertiary and critical for the development of coral reefs (Stanley and Swart, 1995), faces increasing incidence and severity of both sublethal stresses and lethal extreme events. Recent reviews of implications of global climate change for corals and reefs include Done (1999); Buddemeier et al. (2004); Chadwick-Furman (2006); Kleypas and Langdon (2006); Guinotte and Fabry (2008); and Veron (2008). See also below in this article and the Chapter on *Climate Change*.

## Environmental controls on global distribution of corals

Today’s global coral distribution (Figure 1) is in part, a legacy of earlier dispersal and establishment processes (Veron, 1995) and in part, a reflection of habitability constraints imposed by the present day environment, notably, those affecting coral’s capacity to calcify. Light-enhanced calcification requires a particular regime of water chemistry, temperature, and solar radiation. Globally, the coral regions of the world have been ranked along a spectrum of environmental suitability for coral calcification – from “optimal” to “marginal” (Kleypas et al., 1999; Guinotte et al., 2003). Seas with an aragonite saturation ( $\Omega_{\text{aragonite}}$ ) of  $>4.0$  are “optimal” and  $>3.5$  are “adequate,” whereas  $<3.5$  is only “marginal”; sea temperatures  $>18^{\circ}\text{C}$  are warm enough to facilitate polyp replication, gametogenesis, and skeletogenesis; solar radiation needs to be sufficient to sustain a dense population of zooxanthellae with a high production of photosynthate. For these reasons, corals are rare and reefs are absent at latitudes  $>35^{\circ}$  north or south of the equator (Veron, 1995); these latitude’s low sun angles, short winter day lengths, low temperatures, and low aragonite saturation (Figure 1) all militate against vigorous coral growth. The geographic or depth limit beyond which coral growth is vigorous enough for reef growth has been termed the “Darwin Point” (Grigg, 1982).

## Chemistry

A location’s position on the “optimal to marginal” spectrum of Guinotte et al. (2003) reflects the ease or difficulty

**Coral: Environmental Controls on Growth, Figure 1** Global patterns of latitude-correlated environmental controls on coral growth: light, temperature, and carbonate chemistry. Coral reefs are mostly confined to between 35°N and 35°S of the equator and corals between 40°N and 40°S. *Pie diagrams* indicate (in white) the proportion of each year that daily insolation at the sea surface exceeds 200 Einstein per square metre per day (Source: from [Figure 2a](#), after Beer, 1997). The *broken line* indicates position of 18°C sea-surface temperature isotherm in mid-winter (i.e., January average in northern hemisphere; July average in southern hemisphere. Source: Reynolds and Smith, 1995). *Gray shading* indicates northern and southern limits of "adequate" aragonite saturation for coral calcification (source Kleypas et al., 2001).

with which calcium carbonate is deposited by reef plants and animals. It depends in large part on  $\Omega_{\text{aragonite}}$ , the degree to which the sea water is saturated with the ionic precursors of aragonite calcium carbonate – the form comprising the skeletons of reef-building corals:

There is ample  $\text{Ca}^{2+}$  for calcification in all the world's sea waters (Gattuso et al., 1999). (Indeed, excess  $\text{Ca}^{2+}$  is toxic to cellular processes, and biogenic calcification, now the keystone process for coral reef existence, is believed to have initially evolved in the Cambrian as a  $\text{Ca}^{2+}$  detoxification mechanism; Brennan et al., 2004; Kleypas and Langdon, 2006). But the amount of carbonate ( $\text{CO}_3^{2-}$ ) available can become limiting, because it is very easily converted to the unusable bicarbonate ( $\text{HCO}_3^-$ ) in the presence of  $\text{H}^+$  ions: (the lower the pH, the less the  $\text{CO}_3^{2-}$ ).  $\text{H}^+$  ions are evolved when  $\text{CO}_2$  dissolves in water, forming carbonic acid ( $\text{H}_2\text{CO}_3$ ), which then dissociates:

More  $\text{CO}_2$  in solution (Equation 2) means more  $\text{H}^+$  is evolved and more  $\text{CO}_3^{2-}$  is robbed from the feedstock (Equation 1) that could otherwise have been joined with  $\text{Ca}^{2+}$  in the skeleton of a reef-building organism. Temperature also affects the solubility of  $\text{CO}_2$  (and all other gases) in seawater: the warm waters of the tropics absorb less  $\text{CO}_2$  than cool temperate waters, and therefore, less  $\text{CO}_3^{2-}$  is robbed from calcification in the tropics, historically to the great advantage of corals.

### Solar radiation

Solar radiation is a primary environmental driver of production on coral reefs, both organic matter (tissues of plants and animals) and inorganic matter (skeletons), the latter at rates of up to tens of tonnes of calcium carbonate per hectare per year (Kinsey, 1983). The part of the solar radiation spectrum that drives this production is referred to as photosynthetically active radiation (PAR – wave lengths 400–700 nm). Quanta in this range are absorbed by the photosynthetic systems of the zooxanthellae, driving their production of the energy-rich “photosynthate” (glycerol and glucose). Around 95% of the photosynthate is translocated from the zooxanthellae to the cells of the coral host and used throughout the coral colony to build coral tissues, gametes, and aragonite. Calcification occurs at its maximum rate for 4 h around local solar noon (Chalker, 1983), during which time the irradiance of shallow corals with PAR is “saturating” with respect to the ability of the photo systems within the zooxanthellae to use it. The excess irradiance elicits “photoinhibition” in the coral, viz, a reduced photosynthetic efficiency, capacity, or both, compared to the performance at optimal levels of irradiance (Winters et al., 2003). At the high latitude limits of coral distribution, vigorous growth of

“phototrophic” corals (those for which photosynthesis is the primary energy source) is precluded by the meager annual quota of PAR both at the water surface (due to short winter day lengths and low sun angles – Figures 1 and 2a) and at depth (due to reflection and absorption – Baker and Smith, 1982).

### Temperature

Corals are “poikilothermic” organisms (they cannot regulate their temperature and must operate at the ambient temperature). Diverse coral communities and reefs occur in waters with sea temperatures in the range 18–28°C (Figure 2b). Throughout this range, there are suites of corals for which local temperatures are conducive to tissue growth, skeleton growth, and reproduction: the same coral species can host different types (Clades) of zooxanthellae to suit its particular environmental setting. For example, in the tropics, the world's most widely distributed zooxanthellate coral species *Plesiastrea versipora* (Veron, 2000) hosts zooxanthellae that are predominantly of the ubiquitous Clade C (Rodriguez-Lanetty et al., 2001), a highly efficient photosynthesizer (Cantin et al., 2009) that confers a fast growth rate on the many coral species in which it occurs. However, to survive in temperate waters, *P. versipora* hosts predominantly zooxanthellae of Clade B, which can function and survive at lower temperatures than Clade C (Howe and Marshall, 2002). Likewise, some coral species occupy warmer habitats by hosting warm-adapted zooxanthellae, in this case, predominantly Clade D (Berkelmans and van Oppen, 2006; Cantin et al., 2009). Compared to Clade C, however, the tolerance to marginal temperatures in both cases comes at the cost of a reduced growth rate (Howe and Marshall, 2002; Little et al., 2004). This trade-off has permitted corals to spread widely along the latitude-correlated attenuation of the parameters that govern coral growth: viz, temperature, aragonite saturation, and light. Whereas the zooxanthella complement of adult corals is typically dominated by a single clade, juveniles in some coral species host a mixture of clades (Gómez-Cabrera et al., 2008). The extent to which the identity of the clade dominant in the adult represents a form of selection to the type most suited to the individual coral's micro-environment has yet to be established (Gómez-Cabrera et al., 2008).

With normal local seasonal changes in temperature (~5–7°C – Figure 2c), the coral's metabolism is channeled variously into growth and replication of polyps, gametogenesis, skeletogenesis, and manufacture of stored energy reserves (Harriott, 1993). However, a few days of temperatures outside a particular reef's normal variability can be stressful and sometimes lethal for corals, be they abnormally high temperatures or abnormally low. Temperatures only 1–2°C above its normal summer maximum or below its normal winter minimum can cause coral bleaching (Brown, 1997): hot water bleaching (Goreau and Hayes, 1994) or cold water bleaching (Muscatine et al., 1991). In both cases, the anomalous

**Coral: Environmental Controls on Growth, Figure 2** Global and regional variability in reef environments. (b) Annual temperature variation in sea-surface temperatures at a global selection of coral reefs. Source: Elizabeth Reef – Data Centre, Australian Institute of Marine Science, <http://www.aims.gov.au/docs/data-centre/seatemperatures.html>. Remainder: NOAA “Coral ReefWatch” [http://coralreefwatch.noaa.gov/satellite/current/sst\\_series\\_24reefs.html](http://coralreefwatch.noaa.gov/satellite/current/sst_series_24reefs.html). (c) Seasonal variability in sea-surface temperature at reefs at two latitudes on the east coast of Australia. Coastal temperatures are most volatile, and oceanic temperatures are the least.

temperatures can cause expulsion of zooxanthellae, loss of photosynthetic pigments, and subsequent decline of physiological performance, including calcification (Porter et al., 1989), and in severe cases, it can cause death of the coral (Loya et al., 2001). Beyond the latitudinal margins of coral and reef distribution, cold water events, superimposed on low light and aragonite saturation, are sufficiently frequent to cease to be anomalies and to be considered part of a normal seasonal variability that excludes phototrophic corals from establishing and growing, even on suitable substrata. For that reason, the corals on deep cold water reefs lack zooxanthellae, rely entirely on particulate food, and grow very slowly (Roberts et al., 2006).

### Environmental variability within regions

Within the broad bounds set by water chemistry, temperature, and solar radiation (see above), environmental factors affecting coral growth also vary greatly over scales of kilometers to tens of kilometers: nature and depth of the substratum, temperature (Figure 2c), wave climate, salinity, water clarity, nutritional properties of that water, and sedimentation regime. Clear waters have traditionally been considered “optimal” for coral growth, and naturally turbid water reefs “marginal,” but for the purposes of the present account, they are viewed as “just different” (Perry and Larcombe, 2003).

### Hydrodynamics, light, and sediments

Either too little or too much water motion can limit coral growth and survival. Whereas in moderation, water motion facilitates gas and nutrient exchange through the coral’s surface tissues (Atkinson and Bilger, 1992), strong waves and currents cause physical destruction (see *Hydrodynamics in Coral Reef Systems; Tropical Cyclone/Hurricane*), and insufficient flow limits gas and nutrient exchange to the detriment of coral health and survival. Too little flow, which exposes corals to potentially fatal physiological stress, can occur over large areas of the ocean in doldrum conditions. Corals in enclosed reef flats and lagoons are particularly vulnerable to high temperatures, flat glassy waters, and prolonged periods of calm weather. Low- or no-flow conditions thicken the diffusive boundary layer around corals, reduce gas exchange, and make it hypoxic, inducing anaerobiosis in the coral. Moreover, intense light beams condensed by surface ripples can exacerbate the stress caused by high temperatures and low flow, causing corals to bleach at such times (Nakamura and van Woesik, 2001).

Within those habitats where water is in motion, hydrodynamic variables (wave climate, currents, and residence time – see *Hydrodynamics in Coral Reef Systems*) are important determinants of where corals can grow and what morphological form they adopt. In oceanic settings, reefs and islands offer a broad range of environments for corals. Shallow reefs that are exposed to the full force of ocean swells and breaking waves do not necessarily support

significant coral growth. On the outer Great Barrier Reef, for example, corals do build physically robust, wave-resistant structures in the surf break area (Done, 1982). But adjacent areas of the reef are often occupied by coral assemblages consisting of mainly small, short-lived corals, whose longevity is severely limited by recurrent breakage, scour, and abrasion. The latter structure and ephemeral dynamics are comparable to those described for some shallow reef slopes on Oahu, Hawaii, where the turnover of corals is so great that the coral veneer is rarely thicker than a single living colony (Grigg, 1998). The contrast of wave-beaten reefs with those of highly enclosed, shallow reef lagoons and embayments is striking. These latter habitats are often occupied by dense and extensive populations of corals whose shapes, sizes (often large), and longevity (often very great) are extremely variable from place to place, their specific composition dictated by the composition of the regional species pool, founder events, and environmental factors other than waves, such as light, sediments, and currents.

On continental shelves, there are greater complexities of environmental pattern and process, as exemplified in the Great Barrier Reef (GBR), whose 2,900 reefs are distributed across a seafloor that slopes from coastal beaches and headlands to a depth of ~80m at the shelf edge 50–100 km offshore. On most days of the year, big, long period waves generated by distant meteorological drivers surge through interreef passages and break on the outermost reefs. They dissipate strong hydrodynamic forces in the reef’s surf zones and across their tops (Hearn, 1999), and, in conjunction with tidal flows, set up powerful turbulent jets and eddies around their flanks (Wolanski and Hamner, 1988). Depending on reef size, shape, orientation, weather, and state of the tide, different places along the leeward sides of these outer reefs may be completely calm, or they may be impacted by waves from the opposite direction, generated by local winds. These wind waves, which are of smaller wave height and shorter period than the ocean swells, intersect and combine with those oceanic swells that penetrate to behind the outer reefs and then lose height, velocity, and power as they are intercepted by mid-shelf reefs. As they travel into shallow coastal waters, further energy is lost to bottom friction, coarse sediments are rolled along the bottom, and fine sediments are resuspended and mixed through the water column, making it turbid (suspended sediment concentrations of 10–100 mg l<sup>-1</sup> – Larcombe and Carter, 2004). When the winds subside and tides slacken, the coastal waters clear, as suspended sediments fall to the bottom.

### Nutrients

Corals need fixed nitrogen (NH<sup>4+</sup>, NO<sup>2-</sup>, NO<sup>3-</sup>) and phosphate (PO<sub>4</sub><sup>3-</sup>) to synthesize proteins and nuclear material for cell maintenance, growth, and reproduction, and they are well adapted to exploit them in the low concentrations of oligotrophic surface waters in the oceans. However, excess nutrients are detrimental to coral growth

for a number of reasons (Hallock, 2001; Fabricius, 2005): they can limit PAR reaching corals by promoting phytoplankton blooms that reduce water transparency; they can promote the growth of the algal competitors of corals (especially when grazing organisms are scarce); they can promote bioerosion and excessive phosphate can inhibit formation of  $\text{CaCO}_3$  crystals. Excessive N also promotes the proliferation of zooxanthellae within corals (Dubinsky and Jokiel, 1994), which appears to detrimentally affect growth (Lesser et al., 1994) and to increase the coral's sensitivity to elevated temperatures, and thus the likelihood of lethal bleaching (Wooldridge, 2009).

There are four sources of nutrients to coastal waters: rivers, terrestrial dust, rainfall, and upwelled ocean waters. Dissolved concentrations of key nutrient elements required by corals and their zooxanthellae are usually extremely low on coral reefs due to low input rates, huge dilutions, and uptake by phytoplankton and pelagic bacteria (Furnas et al., 2004). Much of the terrigenous nutrient that flows into coastal waters is rapidly incorporated in phytoplankton–zooplankton–fish food webs (Furnas et al., 2004), to the potential benefit of coastal shrimp and fin-fish fisheries. However, the food web itself can deliver excess nutrients into the waters bathing corals: the feeding detritus and fecal pellets generated by this food web are fed on by microbes, which in turn release dissolved nutrients, with the potential to affect corals detrimentally as described above.

### Microenvironment controls on coral growth

A coral's microenvironment consists of (1) *resources* (that it must receive at adequate rates and continuity of supply); (2) *sublethal stresses* (sometimes called “press disturbances” – Connell, 1997), which reduce its capacity to use resources efficiently (e.g., suboptimal temperatures or salinities; low-level pollutants); and (3) *extreme events* (sometimes called “pulse disturbances” – Connell op. cit.), which may kill, injure, or dislodge it during events of short duration (hours to weeks). Extreme natural events, which have characteristic return intervals generally measured in years to decades, include anomalies (high or low) of temperature or salinity, exposure to air (Figure 3), predators (see *Acanthaster planci*), disease, and destructive waves (see *Tsunami*; *Tropical Cyclone/Hurricane*).

On any given reef, corals distribute themselves across ambient environments that are extremely wide ranging, from bright wave-beaten surf zones, across shallow reef tops, and down reef slopes to deep placid twilight zones. Two levels of diversity in the assemblage allow it to occupy such a broad range of environments: the number of available coral species and the plasticity within each species (capacity to adopt a modified form of their basic growth plan). In highly plastic species (the majority), a larva or a fragment will adopt a particular adult growth form that is suited to the precise location in which it happens to settle (e.g., *Acropora humilis*, which adopts

**Corals: Environmental Controls on Growth, Figure 3** Exposure to air – the ultimate environmental limit to the upper limit of coral growth. Corals (several species in the genus *Acropora*) exposed to the air during an extreme low tide event. Wheeler Reef, Great Barrier Reef, July 1986.

a robust form in the surf zone and a lighter structure in deeper waters: *Acropora palmata*, which orients its branches with the waves in the strongest waves, across them in moderate waves, and indifferently to them in calm areas). In species with only one growth form option, the larva or fragment will likely survive only in a single narrowly confined habitat [e.g., *Acropora pyramidalis*, *A. nana* (robust and delicate corals, respectively, found only in surf zones); *Pachyseris robusta*; *Pachyseris speciosa* – encrusting plates, found only in calm waters].

Corals most often attain their highest abundance, percentage cover, and diversity on reef margins (Kinsey, 1983; Macintyre, 2007), i.e., in horizontal zones usually not more than 30-m wide along the edges of intertidal reef flats; on reef slopes, particularly in the upper 20 m and on the margins of lagoonal patch reefs. One reason that corals are abundant in such areas is because these are the habitats that are first encountered by coral larvae carried to the reef by currents. Once established, these corals have first use of waters that flow or break onto the reef. Most aspects of the environment of shallow margins are optimal for coral growth: influx of solar-radiation is nonlimiting; on-flowing water is most saturated in the precursors of coral growth (see Section Chemistry) and richest in the

particulate matter on which corals feed (especially zooplankton); and temperature is the same as the adjacent sea (Figure 2c).

As water crosses the shallow reef, key properties are changed by its interaction with the shallow reef and its biota (see *Hydrodynamics in Coral Reef Systems*). For example, the margin-inhabiting corals (and other calcifying organisms) extract calcium carbonate precursors and nutrients from the water, reducing the levels available to corals “down-stream” (i.e., toward the middle of the reef flat). Calcification by a community reduces the water column’s total carbon and alkalinity, resulting in a decrease of  $\text{CO}_3^{2-}$  (reviewed in Nakamura and Nakamori, 2007). When different reef communities are aligned across a reef from their wave-exposed to their sheltered side, their exchanges with the passing water set up seaward to leeward gradients in pH, total carbon and total alkalinity. In effect, the upstream communities strip  $\text{CO}_3^{2-}$  from the water, limiting its supply to sheltered backwaters, making calcification there impossible. Where corals do grow in such back reef areas, it indicates that seawater with the correct pH, total carbon, total alkalinity, and composition of carbonate species is reaching that place via routes other than a transit across a productive reef flat (e.g., refraction around reef flanks or through broad channels).

Shallow water on reef flats can be easily heated beyond the range preferred or tolerated by corals. This greater temperature volatility is amplified by low-tide ponding and other restrictions on its rate of flushing caused by prior growth of the reef itself (Macintyre, 2007). Where back-reef waters are highly impounded, they can become sinks for rainfall and land-runoff, and for inorganic and organic detritus from the reef upstream, with regimes of temperature, oxygenation, salinity, and turbidity that are inimical for coral growth. Where, by contrast, back-reef habitats are well flushed with ocean waters, corals can grow profusely on sandy lagoon floors and on the margins of back-reef pinnacles and walls.

Solar radiation reaching a coral varies in both space and time, and the key drivers of variability have been reviewed by Anthony et al. (2004): (1) seasonal pattern of daily surface irradiance; (2) variations in clouds; (3) transmittance through the water column, which depends on the optical properties of the water (Baker and Smith, 1982), most notably turbidity; and (4) tides, whose daily and seasonal cycles always affect the depth of the water column and in some circumstances influence turbidity. In a clear oceanic setting, a gradual depth-attenuation of PAR allows corals that are primarily phototrophic to grow to depths as much as 100 m. By contrast, in turbid coastal waters, dissolved and suspended matter attenuates PAR to below useful levels at <20 m. However, corals that gain most of their food by feeding (i.e., heterotrophic corals) can thrive in low light settings, be it deep on a clear water reef or much shallower on turbid water reefs. In both cases, something else may set the lower depth limit to coral distribution; a steep unstable talus in the oceanic reef; a flat muddy sea floor in the coastal reef.

## Coral growth

### From primary polyp to coral colony

There are approximately 700 species of Scleractinian corals globally (Veron, 2000). Based on their adult shapes, they can be divided into six broad “growth-form” categories (Veron, 1996): *massive* (similar in all dimensions); *columnar* (forming columns); *encrusting* (adhering to the substrate); *branching* (arborescent or tree-like to digitate or finger-like); *foliaceous* (leaf-like); and *laminar* (plate-like). There is considerable variability in the detailed morphology among and within species: for example, massive corals may be taller or squatter; columns may be thick or thin, long or club-like; encrustations may be thick or thin; and branches may have different shapes, thicknesses, densities, taper and departure angles of secondary and tertiary branches, which may or may not fuse. A major contributor to this growth form variability is the local environmental setting, which has a comparable effect to that of the coral’s genetic makeup (Veron, 1996) in transformation of the microscopic primary polyp into a flat, fingernail-sized spat, and thence up and out into a particular locally adapted variant of the basic growth form.

The primary polyp develops from a soft-bodied planula larva (see below) that transforms itself into a single soft-bodied polyp within hours of settlement (Hirose et al., 2008), when it glues itself onto something solid (e.g., mollusc shell, dead coral in situ, rubble, rock, or reef framework). The “glue” becomes a perforated shallow calcium carbonate saucer with radial costae (spiky ridges) on top that support the polyp’s tissues. This single act of transformation from soft-bodied larva to skeleton-secreting “zooid” (polyp + skeleton) marks the commencement of a period occupancy that may continue for centuries and produce a colony meters high and meters across.

The adult coral colony that eventually develops has one of the basic growth forms listed above. All except “solitary” corals (in which the original zooid just continues to grow, reaching the size of a desert plate or hefty fruit bowl in a matter of a few years) undergo a process of modular growth. Modular growth occurs through vegetative replication (e.g., budding or expansion, and subdivision) of the original zooid and all of its descendants – Rosen, 1986; Kim and Lasker, 1998). While the basic growth forms are constrained genetically, actual colony morphologies adopted by a particular colony of a particular species in a particular place will in large measure be a phenotypic response to its microenvironment: viz, the regimes of chemistry, nutrition, temperature, and light and wave energy that are incident upon it.

Some large coral colonies originate from an unattached fragment, essentially a small version of the adult colonies, for which the environmental milieu is qualitatively similar to that of the adult. However, being unattached means it can be dislodged, projected, or rolled by strong currents (Fox et al., 2003). In wave-swept reef habitats, where oscillating flows make such motion a daily occurrence, it

usually kills the remaining polyps and the fragment becomes rubble. In habitats where a fragment is immobilized by lodgment in a crevice or falling into a sheltered place, or is inverted only at intervals of weeks to months at most, the living veneer of polyps survives and deposits an increasing mass and volume of skeleton. In shallow flat habitats with reversing currents, a ball-like *corallith* with live polyps on all sides may develop (Glynn, 1974). But in most viable habitats, the fragment will produce skeletal processes that attach it to adjacent stable substratum and prevent further rolling. Once attached, the environmental needs and vulnerabilities are the same as for other attached corals of comparable size.

### Modes of nutrition and coral growth forms

Corals need both large supplies of energy-rich compounds and small amounts of nutrients (N, P) for their growth (tissue and skeleton) and reproduction. Modes of nutrition of corals can be arranged along a spectrum of relative reliance on ingested food as a primary source of energy-rich compounds (Hallock, 2001). In “phototrophic” corals, it is small (but necessary for intake of N and P), and the corals primarily use “photosynthate” (the product of photosynthesis by their symbiotic zooxanthellae). In “heterotrophic” corals, at the other end of the spectrum, there is major reliance on ingested food (zooplankton, organic detritus, and dissolved organic matter). In the middle are “mixotrophic” corals, which use both sources more equally.

Corals build exoskeletons in shapes that facilitate their particular mode of resource use, i.e., adequate interception of solar radiation and particulate food and the water-borne precursors for calcification; use of the moving water to remove the waste products of metabolism. In calm, clear, shallow waters, there is so much light that virtually any shape will be effective in harvesting sufficient PAR. Indeed, these phototrophic corals have to expend energy producing compounds to protect themselves against damaging excess irradiation. However, in wave breaking and surging zones, the range of coral shapes is more limited. These include encrusting forms and/or small colonies of species that adopt a top-heavy form in calmer waters and streamlined and elongated variants of growth forms that are more radially symmetrical in calm waters: e.g., *Acropora palmata* in the Atlantic and several *Acropora* groups in the Indo-Pacific: “*robusta*,” “*humilis*,” “*nasuta*,” and “*palifera*.” Only those shapes that can resist dislodgement by normal fair-weather waves can survive for long, and even they will eventually reach a size where their dislodgement is likely (Massel and Done, 1993; Madin and Connelly, 2006; see also *Tropical Cyclone/Hurricane*).

### Depth and light

In deep or turbid water, phototrophic corals often adopt horizontal growth forms to maximize the interception of PAR. However, in places where this exposes them to

a rain of sediments falling out of the water column, corals survive by adopting shapes that shed sediments passively or with minimal energy expenditure by the polyps: low convex profiles from which gentle water motion can easily entrain sediment particles; dense networks of flattened branches, perforated with gaps through which sediments can drop and vases whose interaction with the currents sets up a vortex that lifts accumulated sediments clear (Reigl et al., 1996). In some species, notably in the genera *Pocillopora* and *Acropora*, colonies in very sheltered habitats have thinner and more open branches than shallower colonies (Veron, 1995; Wallace, 1999), thereby maximizing extension without investing unnecessarily in a strong skeleton.

The PAR dose reaching corals down a reef slope has been attenuated by absorption and scattering as it passes down through the water column (Baker and Smith, 1982). Deeper phototrophic corals compensate for reduced PAR by elevating zooxanthellae densities, chlorophyll content per zooxanthella, or both. These changes cause them to appear more darkly colored than shallow water corals. In clear waters, corals as deep as several tens of meters can remain saturated and function normally (Chalker, 1983).

In turbid waters, this depth may be only a few meters. There, the day-to-day and week-to-week variation in irradiation a few meters down the slope can, due to frequent resuspension of mud from the adjacent shallow sea floor, be more than an order of magnitude greater than it is at the surface and at equivalent depths in offshore, clear-water benthic habitats (Anthony, 2000; Anthony et al., 2004). Corals on slopes of turbid-water reefs may thus alternate between periods of light deficiency and light excess. Phototrophic corals are therefore confined to the relatively well-lit shallower parts of such reefs, whereas deeper, darker, and muddier parts of these reefs are populated by corals with specific adaptations for those conditions. In very dark (deep or very turbid) waters, only mixotrophic or heterotrophic corals can survive (Anthony, 2000). These corals largely replace the now minimal zooxanthellae-derived photosynthate as the primary food source with dissolved organic matter (saprohagy) or particulate organic matter (detritus and/or zooplankton) (Anthony et al., 2004). In deep (50–4,000 m), dark cold-water coral reefs (4–12°C), approximately ten species of scleractinian corals have been discovered, all completely lacking zooxanthellae (Roberts et al., 2006). They rely entirely on food transported from surface waters to the sea floor, frequently in sites with food supply enhanced by locally accelerated currents.

Ultraviolet radiation (UVR – 390–400 nm) is potentially damaging to corals. However, a number of things protect corals from UVR damage. First, is depth itself: shorter wavelengths are scattered by particles and absorbed by water molecules and dissolved organic compounds more readily than PAR wavelengths (Baker and Smith, 1982). As a result, UVR attenuates to near zero within a few meters at most, and because of the extreme

scattering, they irradiate the corals only weakly. Second, shallow corals manufacture sunscreens [mycosporine-like amino acids (MAAs) – Dunlap and Shick, 1998] that shield their tissues from any ambient UV that does reach them. These compounds are especially important for those corals that are periodically left emerged at extreme low tides (Figure 3) and thereby exposed to direct sunlight. Some of the MAAs produced by the corals occurs in mucus that is secreted by emergent corals and protects them from dehydration.

### Environmental controls on coral's presettlement stage

The environmental milieu of the coral's presettlement stage is quite different to that of adult corals. Corals develop by two main methods (Harrison and Wallace, 1994; see also *Corals: Biology, Skeletal Deposition, and Reef-Building*): asexually (from the fragments of an existing colony that become separated by budding or breakage from a parent colony – see Section Coral growth) and sexually (from fertilized eggs that grow into pelagic larvae that swim or are carried by currents to their place of settlement). Pelagic coral larvae are released into the water by sexually mature corals (usually >3–5 years old) that produce sperm and eggs. Depending on species, the production of the larvae follows one of the two pathways (1) broadcast spawning or (2) brooding. In broadcast spawning, gravid polyps expel eggs and sperm into the water column during a mass spawning event whose timing is synchronized to lunar cycles. Fertilization takes place in the water column, and the drifting fertilized egg transforms itself into a planula larva over a period of several days (Hirose et al., 2008). During its days in the currents, the metamorphosis from egg to larva is fueled by lipids originating from the egg. Once it has developed its simple gut (~4 days), it can feed on phytoplankton and detritus and presumably does so if it is nowhere near a suitable place to settle (Richmond, 1987). However, at this stage it is competent to settle (Hirose et al., 2008), and it tends to do so quickly when deprived of food in the laboratory (Hirose et al., 2008). When food is supplied, individuals of some species can settle within 2–3 days (Miller and Mundy, 2003). For those that do not settle so quickly, there can be major mortality within the first few days, but survival of others in the water column upwards of 100 days (Graham et al., 2008). During this time they are potentially exposed to environmental hazards such as hyposaline areas, excessively muddy areas, or very clear areas where they may become exposed to damaging doses of UVB radiation (Gleason and Wellington, 1995). In open waters between reefs, they will likely be aggregated into fronts generated by the current's interaction with headlands, islands, and reefs; this aggregation on one hand attract predatory fishes or shrimps, but on the other, take cohorts of competent larvae to potential settlement sites (Wolanski and Hamner, 1988). The broadcast-spawning strategy described above favors colonization of widely dispersed

reef substrata and hence the maintenance and/or restoration of those area's reef-building potential (see *Coral Reef, Definition*).

The brooding strategy, by contrast, leads to localized settlement that favors persistence of the local population and local reef-building. In brooding coral species, fertilization takes place within the polyps of the parent colony and so does metamorphosis into the planula larva (Harrison and Wallace, 1994). When expelled several days after fertilization, they are strong swimmers, zooxanthellae bearing, and competent to attach to the reef within minutes to hours of release: they avoid the hazards of days to weeks in the water column that are faced by broadcast pelagic larvae. Brooded larvae have much higher likelihood of finding a suitable settlement place, in this case, close to one that has been tried and tested by the parent colony.

When broadcast larvae are swept over a reef from the sea on a flooding tide, they face the environmental hazard of "the wall of mouths" (Hamner et al., 1988) belonging to coral polyps (Fabricius and Metzner, 2004) and schools of planktivorous fishes that ride the surge along reef edges (Hamner et al., 2007). Those that survive will then receive environmental cues to a potential place for settlement. A hydrodynamic cue alone (Abelson and Denny, 1997) may attract them to within centimeters of solid substrata. Their choice of specific microcrevices may then be guided by chemical cues emitted by coralline algae and microbial films coating the substratum (Harrington et al., 2004). Abelson and Denny (1997) suggest that when hydrodynamic forces are higher than the larva's swimming capacity (as may often be the case in wave-swept reef environments), final site selection may be due to desertion of unfavorable sites rather than exploration and active selection of an appropriate site. For many species it is only after the coral larvae has settled and transformed itself into a rudimentary polyp that it acquires zooxanthellae that multiply within its tissues (Hirose et al., 2008) and contribute to the nutrition of their host.

Reef environments present a wide range of colonizable substrata for the establishment of corals that could occupy that place for decades or even centuries. In wave-swept parts of the reef, the substratum to which a coral attaches is usually big and heavy enough to stay in place against normal hydraulic forces generated by waves (e.g., solid framework and heavy rubble). In sheltered parts of the reef, smaller rubble sizes (coral shingle and mollusc shells) can be colonized by coral larvae, and even sand and mud can be colonized by coral fragments of some species.

### Global climate change: implications for coral growth

The net effect of global warming and increases in atmospheric CO<sub>2</sub> per se are detrimental to the biological calcification process (Feely et al., 2004; Hoegh-Guldberg et al., 2007; Guinotte and Fabry, 2008). There is so much more

atmospheric CO<sub>2</sub> at the ocean–atmosphere interface today (385 ppm in 2010) compared to preindustrial times (280 ppm) that much more goes into solution, despite the marginal solubility loss caused by increased sea temperature (Sabine et al., 2004). These authors report that if CO<sub>2</sub> reaches double preindustrial levels (560 ppm), there will be a 30% decrease in carbonate ion concentration and a 60% increase in hydrogen ion concentration. There are likely to be differences among calcifiers in their responses to decreasing carbonate ion concentrations, reflecting differences in their carbonate mineralogy and local environmental parameters such as temperature, light, and available nutrients and in the mechanism of biomineralization (Feely et al., 2004). A review by Guinotte and Fabry (2008) suggests that this would cause a 20–60% reduction of calcification rates in tropical reef-building corals, manifest in the skeleton in its two measurable parameters: rate of linear extension (cm day<sup>-1</sup>) and density (g cm<sup>-3</sup>) (Barnes and Chalker, 1990; Lough and Barnes, 2000). Any loss of density would cause a decrease in strength and greater vulnerability to storms in corals on the reef (Massel, 1999). A reduction in linear extension rate would mean that individual colonies would take longer to reach size-related thresholds, such as sexual maturity (Albright et al., 2008), escape from overgrowth by other benthos, or vulnerability to dislodgment by storm waves (Massel and Done, 1993; Madin and Connelly, 2006). Most recent field studies have shown a reduction in linear extension and density coincident with rising temperature and atmospheric pCO<sub>2</sub> over recent decades (Cooper et al., 2008; De'ath et al., 2009; Tanzil et al., 2009). A number of studies (noted in Albright et al., 2008) have reported that reduced calcium carbonate saturation has no negative effect on physiological processes other than calcification (viz, tissue growth and photosynthesis) and indeed may even augment them. Paradoxically, any decline in reef-wide calcification caused by atmospheric CO<sub>2</sub> will reduce aqueous CO<sub>2</sub> emanating from the reef itself. Reefs as a whole, including their reef flats and lagoons, tend to be sources of CO<sub>2</sub>, due both to calcification by reef communities and the decomposition of plant matter produced on the reef (Suzuki and Kawahata, 1999).

Anthropogenic climate change may be precipitating the sixth great coral reef extinction in 430 million years (Veron, 2008). Reefs are confined to warm shallow waters that are becoming too hot too often, bleaching and killing coral populations on reefs scattered over vast areas of ocean. As a result, recolonization of damaged areas will be weakened, and even in those places where by chance there is good recolonization, the next heatwave, hurricane, flood, pest outbreak, or disease will cut off recovery of high coral cover before it can be completed. Refuge populations themselves are threatened. For shallow ones, it may simply be a matter of time before they are killed by a heatwave, and for deeper and cooler ones, before they become victims of shallowing of the aragonite saturation zone caused by ocean acidification (Feely et al., 2004). This view of the future – predicated on the assumption

that environmental changes will be too great and are occurring too fast for there to be any effective adaptation in reef organisms (see Chapter *Adaptation*) – raises some key questions about the viability of the processes and circumstances responsible for maintaining modern coral reefs, i.e., environmental controls on coral growth.

## Summary

Coral growth (individuals, populations, and communities) responds to variations in their external environment that are manifest over spatial scales spanning centimeters to degrees of latitude. The specific microenvironment in which a coral settles and in which it may spend anything from years to centuries is determined by vagaries of currents and early survival. Corals and coral reefs exist within a range of local settings within a region (e.g., oceanic vs. continental shelf) and benthic communities and reefs further modify their own environments – dissipation and refraction of waves; ponding of reef-top waters; removal of aragonite precursors and addition of organic and inorganic detritus. As a result, there may be as much variability in the range of microenvironments existing within regions and on individual reefs as there is across much broader geographic areas. This existing variability in microenvironments and the concomitant diversity in species and coral–zooxanthellae partnerships are extremely important for the survival of reefs in a future with global climate change, in which they are faced with rapid changes in environment over all spatial scales.

### Definition

Many massive corals contain annual density bands in their calcium carbonate skeletons, similar to tree rings. Growing at  $\sim 1\text{--}2$  cm/year coral bommies<sup>1</sup> several meters in height can contain several hundred years of continuous coral growth. The annual density bands (visible when slices from coral are X-rayed) provide the chronological control for the extraction of a wealth of high-resolution coral growth and coral paleoclimatic records. These make a substantial contribution to understanding the nature and causes of climate variability and change, in the shallow-water tropical ocean regions, prior to the advent of extensive observational records and complement similar records obtained from tree rings, ice cores, and documentary sources.

Accessing this information requires a sample from the coral and bigger, older corals will provide data over a longer time span (Figure 1). The preferred sampling technique requires the extraction of a core from the coral colony with a tubular drill rig (Figure 2). The corer cuts through the concentric layers of colony growth and when the core is removed, a hole through the colony is created from the living surface to the base. The living tissue of

the coral only occupies the outer 0.5–1.0 cm of the colony (the layers below are dead but retain their physical structure), so taking a core 90 mm in diameter removes  $\sim 63\text{ cm}^2$  of live coral.

Holes left by coring activities create opportunities for boring organisms to invade a colony and provide a place for sediment to collect and both of these possibilities may cause long term damage to the colony. Many workers seal the core holes with a solid plug to prevent borer access and eliminate sediment collection. Concrete is mostly used to make tapered, cylindrical plugs, slightly larger than the core hole at the big end and slightly smaller at the other end. This taper allows the plug to fit tightly into the hole and remain firmly in place as the coral continues to grow. The plugs are made well before use and soaked in sea water for a month to eliminate soluble components that could damage the coral (Figure 3).

Studies on the Great Barrier Reef (Australia) over a 3 year period have shown that colonies of *Porites* (sp) are not damaged by the plugs and are able to grow over the concrete plugs completely. The rate of regrowth is dependent on the coral species and prevailing environmental conditions. The relief of the plugs is also important; plugs that sit flush with the colony surface are more likely to be grown over, than those that are higher than the surrounding coral structure (Figure 4). In the GBR study which looked at *Porites* regrowth after 50 mm diameter cores were taken, the shortest time taken to completely grow over the concrete plug was  $\sim 30$  months, whilst others were still less than half covered after 36 months. A small

**Core Plugs, Figure 1** Cores taken from massive, long lived corals like this *Porites* sp. can provide data about climatic conditions that pre-date instrumental records.

**Core Plugs, Figure 2** Cores are extracted from the colony using a variety of methods, shown here is a powerful hydraulic drill rig clamped in place with the operator about to commence cutting.

**Core Plugs, Figure 3** When the core has been removed, a hole is left in the colony and this is plugged with a tapered, conical, concrete plug. These plugs are pre-washed in sea water to eliminate soluble toxins and are hammered home in level with the natural surface.

**Core Plugs, Figure 4** The *upper portion* of this image shows part of a colony cored and plugged a month before the photo was taken. The *lower portion* of the image shows the same colony 36 months later. The healthy coral has continued growing normally and covered both plugs completely.

number of the colonies showed no growth on the concrete plugs at all.

One of the cored colonies had no plug and acted as a control. This colony not only had apparent damage which could be attributed to the coring activity, but also showed very little of the horizontal growth evident, where plugs were used.

Cores taken from massive long lived corals can provide valuable paleoclimatic information and coral growth histories. The value of these cores must be weighed against the potential risk to the colonies from which the cores are extracted. Sealing the core holes with tapered concrete plugs that have been conditioned by long pre-immersion in sea water reduces the likelihood of long-term damage to cored colonies and in many cases assists the colony to overgrow the damaged area in a relatively short time.

<sup>1</sup>The term “coral bommie” is used in Australia to describe large outcrops of coral often visible from the surface, usually separated from the main reef. In this article, it refers specifically to individual, living colonies of the *Porites* genus as seen in [Figure 1](#).

## DALY, REGINALD ALDWORTH (1871–1957)

---

Tom Spencer  
University of Cambridge, Cambridge, UK

Reginald Aldworth Daly (1871–1957) Canadian igneous petrologist, structural geologist, early geophysicist, and originator of the glacial control hypothesis for the origin of modern coral reefs. Educated at Victoria College, Ontario and Harvard University (PhD 1896), where he was a teaching assistant under N.S. Shaler and W.M. Davis. In 1901, he joined the Canadian International Boundary Survey and undertook a monumental survey of structural geology along the 49th Parallel from the Pacific coast through the Cascades and Rocky Mountains into the Great Plains. In 1907, he returned to academic life, first taking a position at Massachusetts Institute of Technology, and then succeeding Davis as Sturgis Hooper Professor at Harvard in 1912, a post he held until his retirement in 1942.

In 1909, he undertook (with T.A. Jaggar, founding Director of the Hawaii Volcano Observatory) early studies of Kilauea volcano, Hawaii and as a member of the Shaler Memorial Expedition to the southern hemisphere (1921–1922), he mapped the volcanic islands of St. Helena and Ascension and studied the Bushveld intrusion in South Africa, the latter leading him to become a supporter of the theory of continental drift. In 1919, on a Carnegie Institution – funded expedition with A.G. Mayor, he mapped the geology of American Samoa. Other interests included carbonate sedimentation and beachrock (with field studies at the Tortugas Marine Laboratory, Dry Tortugas, Florida), turbidity currents and the formation of submarine canyons,

and isostasy and glacial rebound (supported by evidence from raised shorelines in Canada and Fennoscandia). He made a major contribution to coral reef science through the glacial control hypothesis (see [Glacial Control Hypothesis](#)) which drew attention to the importance of Pleistocene variations in sea level and ocean temperature in determining the morphology of modern coral reefs; while many of his inferences on the magnitude of Pleistocene environmental change have been shown to be broadly correct, he overestimated its impact on coral reef morphology.

## DANA, JAMES DWIGHT (1813–1895)

Tom Spencer

University of Cambridge, Cambridge, UK

James Dwight Dana (1813–1895) American geologist, mineralogist, and naturalist. Holder of the Silliman Professorship of Natural History and Geology at Yale College, 1850–1892. Dana was geologist and mineralogist of the United States Exploring Expedition commanded by Charles Wilkes (1838–1842), gaining field experience of volcanoes and coral reefs in Madeira, Kiribati, Tuvalu, the Tuamotu Archipelago, the Society Islands, Samoa, Tonga, Fiji, and the Phoenix and Hawaiian Islands. His expedition reports, published in large volumes with elaborate plates and an atlas, included Zoophytes (1846), Geology (1849), and Crustacea (1852–1855). Dana was the foremost American geologist of his time, writing more than 200 books and published papers, and he held an influential position as editor of the *American Journal of Science*. His highly popular “On Coral Reefs and Islands” published in 1853 (revised as “Corals and Coral Islands” (1872, then 1890)), established coral reefs as a legitimate object of scientific inquiry in North America. One of the key elements in Dana’s writings was his strong support for the Darwinian theory of coral reef development. He tried to refine Darwin’s estimate of the area of the Pacific Ocean characterized by subsidence (as evidenced in Darwin’s (1842) maps of the distribution of barrier reefs and atolls) and came to the remarkable conclusion, prefiguring modern plate tectonic theory, that subsidence had increased across the Pacific Ocean basin from south to north. He recognized the morphological evidence for the sequence of island ages in the Hawaiian Islands and was the first to argue for the paucity of reef development on the eastern sides of the ocean basins as a result of the presence of cool sea surface temperatures. As the “outstanding fluvialist” (Chorley et al., 1964, p. 367) of the mid-nineteenth century, he recognized the fluvial dissection of mid-ocean volcanoes and the relation of valley development and stream density to rainfall patterns on windward and leeward volcanic slopes. His observation that island subsidence would lead to an irregular coastline with large embayments, as commonly seen on volcanic islands lying within barrier reef lagoons, was a powerful proof in favor of the subsidence theory, as recognized by Charles Darwin himself.

## DARWIN POINT

Richard W. Grigg

University of Hawaii, Honolulu, HI, USA

## Darwin Point

Darwin Points are drowning thresholds for coral reefs and coral islands that have existed in the world oceans since the evolution of reef building corals at the beginning of the Mesozoic Era ~240 Ma (Grigg, in press). A Darwin Point is reached when the net production or vertical accretion rate of CaCO<sub>3</sub> by reef building corals no longer keeps pace with relative sea level. A Darwin Point is exceeded when the reef structure permanently drowns. Drowning occurs when production rates due to coral growth are exceeded by rates of bio-erosion, physical-induced losses, rates of island subsidence, or sea-level rise. During the last transgression, the sea level rose on the order of 130 m (21,000 years B.P. to the present), and many coral reefs in the world drowned. Another classic example where a Darwin Point exists is the northwestern end of the Hawaiian Archipelago (Grigg, 1982) (see [Figure 2](#) in the entry *Hawaiian Emperor Volcanic Chain and Coral Reef History*), beyond which atolls drown and become guyots. Even older and deeper examples are the numerous guyots that dot the northwestern Pacific Ocean that today make up, in part, the Mid-Pacific Mountains (Flood, 1999).

Clearly, there are many causal factors that potentially produce “Darwin Point events,” and there is an abundant literature on the question of why coral reefs fail (drown) (Chave et al., 1972; Hopley, 1982; Grigg and Epp, 1989; Grigg, 2006). In the modern day, perhaps the most common examples of Darwin Points are the vertical depth limits of reef building corals set by light extinction or a combination of factors including light extinction, bio-erosion, temperature stratification, or sedimentation ([Figure 1](#)). Looking at the future and to the possible effects

**Darwin Point, Figure 1** Vertical Darwin Point of the major reef building coral, *Porites lobata*, in the Au'au Channel, Maui, SE Hawaiian Islands (Grigg, 2006).

of Global Climate Change, it also seems plausible that many more coral reefs may fail in the not too distant geological future (Mackenzie, 2003).

## DARWIN, CHARLES (1809–1882)

Nick Harvey  
 The University of Adelaide, Adelaide, SA, Australia

*Charles Darwin*. British naturalist, 1809–1882, developed subsidence hypothesis for reef development.

## Introduction

Charles Darwin had a profound effect on the theories of coral reef evolution and the subsequent pattern of reef research. In 1842, after some delay due to his ill health, the first edition of Darwin's *The Structure and Distribution of Coral Reefs* was published. In the introduction of the book, Darwin describes its objectives as “to describe from my own observation and the works of others; the principal kinds of coral reefs, more especially those occurring in the open ocean, and to explain the origin of their peculiar forms” (Darwin, 1842, p. 1).

Darwin provides the reader with an explanation for different types of reefs; “lagoon islands” or “atolls,” “barrier,” or “encircling reefs,” and “fringing,” or “shore reefs” (see [Subsidence Hypothesis of Reef Development](#)), for each of which he dedicates a separate chapter (Darwin, 1842). In the introduction to the book, he also provides a brief overview of his theory of coral reefs, including barrier reefs for which at that time, according to him, there was “scarcely one” (Darwin, 1842, p. 4). Thus, according to Darwin “. . . in both atolls and barrier-reefs, the foundation on which the coral was primarily attached, has subsided; and that during this downward movement, the reefs have grown upwards. This conclusion, it will be further seen, explains most satisfactorily the outline and general form of atolls and barrier – reefs, and likewise certain peculiarities in their structure” (Darwin, 1842, p. 4). (see Chapter [Subsidence Hypothesis of Reef Development](#)).

This work was not the first time Darwin's ideas on coral reefs had been published. In the introduction to the book, Darwin writes that “A brief account” of his ideas on corals was read to the Geological Society of London in May 1837 and subsequently published in the *Proceedings* (Darwin, 1838). His ideas were also published in the third volume of Fitzroy (1839).

## Voyage of the Beagle and Darwin's coral reef theory

Darwin's theory on coral reefs originally formed during the famous voyage of the Beagle (1831–1836), with Robert Fitzroy as Captain/Commander and Surveyor (Fitzroy, 1839). Fitzroy received his "instructions" for the voyage from the "Lords Commissioners of the Admiralty":

"You are hereby required and directed to put to sea, in the vessel you command, so soon as she shall be in every respect ready, and to proceed in her, with all convenient expedition, successively to Madeira or Teneriffe; the Cape de Verde Islands; Fernando Noronha; and the South American station; to perform the operations, and execute the surveys, pointed out in the accompanying memorandum, which has been drawn up under our direction by the Hydrographer of this office; observing and following, in the prosecution of the said surveys, and in your other operations, the directions and suggestions contained in the said memorandum." (Extract from "Instructions" in Fitzroy, 1839, p. 22).

As pointed out by Chancellor (2008 np), coral reefs "...were in fact one of the key scientific objectives of the *Beagle's* orders from the Admiralty." Certainly, the undertaking of coral reef investigations on the voyage were detailed in the "memorandum" accompanying the instructions:

The circularly-formed Coral Islands in the Pacific occasionally afford excellent land-locked harbours, with a sufficient entrance, and would be well adapted to any nice astronomical observations. . . While these are quietly proceeding. . . , a very interesting inquiry might be instituted respecting the formation of these coral reefs.

An exact geological map of the whole island should be constructed, showing its form, the greatest height to which the solid coral has risen, as well as that to which the fragments appear to have been forced. The slope of its sides should be carefully measured in different places, and particularly on the external face, by a series of soundings, at very short distances from each other, and carried out to the greatest possible depths, at times when no tide or current can affect the perpendicularity of the line. A modern and very plausible theory has been put forward, that these wonderful formations, instead of ascending from the bottom of the sea, have been raised from the summits of extinct volcanoes; and therefore the nature of the bottom at each of these soundings should be noted, and every means exerted that ingenuity can devise of discovering at what depth the coral formation begins, and of what materials the substratum on which it rests is composed. The shape, slope, and elevation of the coral knolls in the lagoon would also help the investigation; and no circumstances should be neglected which can render an account of the general structure clear and perspicuous. (Extract from "memorandum" in Fitzroy, 1839, p. 38).

Charles Darwin's presence on the Beagle's voyage was precipitated by Fitzroy's anxiousness "... that no opportunity of collecting useful information, during the voyage, should be lost..." so Fitzroy "... proposed to the Hydrographer that some well-educated and scientific person should be sought . . . . . Captain Beaufort approved of the suggestion, and wrote to Professor Peacock, of Cambridge, who consulted with a friend, Professor Henslow, and he named Mr. Charles Darwin, grandson

of Dr. Darwin the poet, as a young man of promising ability, extremely fond of geology, and indeed all branches of natural history." (Fitzroy, 1839, pp. 18–19). In Fitzroy's (1839) list of persons aboard the Beagle when it sailed from England, Darwin was listed as "naturalist."

During the voyage of the Beagle, Darwin visited South America in 1834–1835. He was strongly influenced by Lyell's *Principles of Geology* published in 1832 in which Lyell dedicated the final chapter to coral reefs. (see Chapter *Lyell, Charles (1797–1875)*). Influenced by Lyell's work, Darwin noted the effects of intermittent uplift on the land together with erosion and deposition of sediments. From this, he speculated on the effects of subsidence upon the upward growth of corals and made some outstanding deductions before he had ever seen a coral reef. He deduced that progressive island subsidence could transform a fringing reef into a barrier reef and finally into an atoll. According to Harvey (1982, p. 3) Darwin's deductive model was confirmed when he visited Tahiti in November 1835 and viewed the island of Moorea from the neighboring slopes behind Papeete. He saw the central volcanic island surrounded by a lagoon, which in turn was encircled by a barrier reef. He deduced that with progressive subsidence of the central volcanic island the encircling reef would slowly grow upwards until the central lagoon had disappeared altogether leaving only a circular rim of coral with a central lagoon. Thus, the theoretical development of fringing reefs to barrier reefs and finally to atolls overcame the problem of explaining the anomalously great depths at which shallow water reefal limestones had been found.

The same sequence of reef development was not readily applicable to continental margin reefs such as the Great Barrier Reef (GBR). Harvey (1982) notes that Darwin never visited the GBR although following the visit to Tahiti, the Beagle on her homeward journey sailed around the southern shores of Australia. Darwin did, however, attempt to relate his subsidence theory to the GBR, suggesting that it "may have been important in the Reef's evolution. Although he was not able to test this hypothesis, the importance of his subsidence theory deduced from Pacific atolls and the debate that followed its publication had a profound effect upon research in the Great Barrier Reef Province" (Harvey, 1982, p. 3).

## A deductive theory

As noted by Chancellor and van Wyhe (2008) and Harvey (1982), Darwin's ideas on coral reefs had been formed before he had seen one. Chancellor and van Wyhe (2008) comment that Darwin's "Santiago Notebook" "...has been quoted from by many scholars in connection with the famous passage which confirms that Darwin had thought out his coral reef theory before seeing a coral island, as he claimed in his *Autobiography*...". In the autobiography, Darwin wrote:

No other work of mine was begun in so deductive a spirit as this; for the whole theory was thought out on the west coast of

S. America before I had seen a true coral reef. I had therefore only to verify and extend my views by a careful examination of living reefs. But it should be observed that I had during the two previous years been incessantly attending to the effects on the shores of S. America of the intermittent elevation of the land, together with denudation and the deposition of sediment. This necessarily led me to reflect much on the effects of subsidence, and it was easy to replace/in imagination the continued deposition of sediment by the upward growth of coral. To do this was to form my theory of the formation of barrier-reefs and atolls. (Darwin, 1958, pp. 98–99)

## Second edition of “Coral Reefs”

In 1874, a revised second edition of *Coral Reefs* was published. Darwin writes that in the second edition, he has “added some new facts and have revised the whole book; the latter chapters having been almost rewritten” (Darwin, 1874, p. viii). According to Freeman (1977), this was influenced by the work of Professors Dana and Jukes. Certainly, Darwin writes that since the 1842 publication, “only one important work on the same subject has appeared, namely, in 1872, by Professor Dana, on *Corals and Coral-Reefs*”. In the preface, he discusses some of Dana’s assertions and criticisms of his (Darwin’s) work. Of Professor Dana, Darwin comments that

Although I thus demur to some of the remarks and criticisms made by this eminent naturalist, who has examined more coral formations than almost any other man, yet I do not the less admire his work. It has also afforded me the highest satisfaction to find that he accepts the fundamental proposition that lagoon islands or atolls, and barrier-reefs, have been formed during periods of subsidence (Darwin, 1874, p. vii).

Darwin, in the preface to the second edition, quotes Jukes as saying Darwin’s “hypothesis is perfectly satisfactory to my mind.” However, Darwin suggested that the “distinguished naturalist, Professor Semper, differs much from me, although he seems willing to admit that some atolls and barrier-reefs have been formed in the manner in which I suppose” (Darwin, 1874, p. vii).

## Conclusions

Although the basics of Darwin’s theory have since been proven by deep borings and geophysical surveys on many open ocean atolls, his theory initiated a great deal of debate centered mainly around the substrate from which reefs grew. This debate resulted in alternative theories (see Chapter *Subsidence Hypothesis of Reef Development*) or new ideas which added to Darwin’s theory. While there are various reviews of these (e.g., Cotton, 1948; Harvey, 1982; Hopley, 1982) the fundamentals of his theory remain, and Darwin’s works represent perhaps the most important nineteenth century contribution to the study of coral reefs.

## DAVID, TANNANT EDGEWORTH (1858–1934)

---

Peter J. Davies  
 School of Geosciences University of Sydney, Sydney,  
 NSW, Australia

Professor of Geology at the University of Sydney (1891–1924), Tannant Edgeworth David was born in St. Fagans, South Wales as the eldest child of the Rev. William David and his wife Margaret Harriette, née Thomson, from whose family came the names Tannant and Edgeworth.

David entered New College, Oxford in 1876 and gained a first class in classics in 1878; however, a breakdown in health prevented him from reading for final honors. While convalescing, he traveled to Canada and then on a round trip to Melbourne in the sailing ship *Yorkshire*. Back at Oxford, David attended Professor Joseph Prestwich’s lectures on geology before graduating

**David, Tannant Edgeworth (1858–1934), Figure 1** David, Tannant Edgeworth.

B.A. in 1881 (M.A. 1926). He returned to Australia in 1882 on the steamship *Potosi* arriving at Sydney on the 27th November to join the New South Wales Government as assistant geological surveyor. He married Caroline Martha (Cara) Mallett on the 30th July 1885 at St Paul's Church of England, Canterbury, having met her earlier on the voyage to Sydney in 1882. Edgeworth David joined the University of Sydney as Professor of Geology and William Hovell Lecturer in Physical Geography in 1891 (Figure 1).

Within his first decade as Professor at the University of Sydney, Edgeworth David enjoyed world wide repute, chiefly as a result of his work on Funafuti Atoll in the Ellis Islands. Always the opportunist, David saw as a challenge the 1896 failure of the party sent by the Royal Society of London to bore a deep section at Funafuti. Excited by Darwin's 1842 assertions that coral reefs were shallow water structures built on sinking foundations, Edgeworth David raised the necessary funds for an expedition from Sydney equipped with diamond drills made available by the New South Wales Government: the scientific objective was to drill a deep hole through the reef to test this assertion. In June 1897, David left for Funafuti, accompanied by his wife Mrs. Cara David, George Sweet (a practical engineer and amateur scientist), two senior students, and a party of workmen. After many difficulties, not all of them mechanical, the drilling reached a depth of 177 m before David returned to Sydney, leaving Sweet in charge; thereafter, Mr. Sweet extended the hole to a depth of 213 m before the workmen refused to continue. The following year, David sent another party to "finish the job" and the party cleaned and deepened the hole to a final depth of 339 m.

The drilling showed conclusively, both at the time and since, that the entire section drilled to 340 m is comprised of shallow water organisms; indeed, the first indications of the importance of *Halimeda* in producing carbonate came from cores taken at Funafuti Atoll in 1904. A core drilled into the reef to a depth of 339 m was mostly composed of *Halimeda* and other calcareous algae. This evidence gave striking support for *Charles Darwin's* theory that coral atolls had grown progressively under the influence of subsiding platforms. It did not however show that the subsiding platforms were volcanic based, a conclusion proved much later in the mid-twentieth century.

Although the main technical reports on Funafuti did not appear until 1904, David's part in the venture was recognized by the award of the Bigsby medal by the Geological Society, London, in 1899; next year the Royal Society, London, admitted him a fellow. Mrs. Cara David published an "unscientific account" of the expedition, *Funafuti: Or, Three Months on a Coral Island* (1899).

Following the Funafuti work, David worked in Antarctica with Shackleton and was the first to the south Magnetic pole; he later mapped the New South Wales coal fields, directed the Allies underground Trench systems in the 1914–1918 War and wrote the definitive first work on the Geology of Australia. He was knighted in 1920 and became known as Sir Edgeworth.

Tannant Edgeworth David retired from the University of Sydney in 1924 and died in Sydney in 1934 at the age of 76.

## DAVIS, WILLIAM MORRIS (1850–1934)

---

Tom Spencer  
 University of Cambridge, Cambridge, UK

American geographer, geologist, meteorologist but fundamentally the leading figure in the development of the

study of landforms – geomorphology – between the 1880s and 1930s.

### Davis and Coral Reefs

William Morris Davis (1850–1934) was the dominant figure in the development and codification of geomorphology (the science of the study of landforms and the processes that form them) from the last decades of the nineteenth century, responsible for the concept of the “cycle of erosion” whereby landforms pass progressively, irreversibly, and predictably through the stages of “youth”, “maturity”, and “old age”. Following his resignation from the Sturgis Hooper Professor of Geology at Harvard University in 1912 (where he was succeeded by R. A. Daly), his scientific focus became strongly reef-based; he published over 50 items on coral reefs between 1913 and 1934, including a major treatise, ‘The Coral Reef Problem’, published in 1928. Much of this work was desk-based and theoretical, but he undertook a 9 month cruise to Pacific reefs in 1914 (including visits to Hawaii, Fiji, New Caledonia, the New Hebrides, New Caledonia, and the Great Barrier Reef (where a visit to Green Island, Great Barrier Reef was dismissed as “an entertaining experience, but, as might have been expected, entirely fruitless as far as the origin of the reef is concerned” (Davis, 1928, p. 347)), Rarotonga and Tahiti) and a shorter visit to the Caribbean in 1923. He was totally supportive of Darwin’s subsidence theory, promoted J. D. Dana’s “principle” of the importance of the embayed shorelines as evidence for volcanic island subsidence and made useful observations on the cliffs of volcanic islands on the margins of the reef seas, which he attributed to a lack of reefal protection during glacial stages. As P. B. King perceptively pointed out (see King and Schumm, 1980), his analysis had most conviction when dealing with the relatively simple tectonic settings of oceanic reefs but struggled elsewhere. Thus, as Stoddart (1994) has argued, he systematically misrepresented the geomorphic history of elevated reef islands in Fiji, Tonga, the Loyalty Islands and the southern Cook Islands, from no or very limited field observations, erroneous assumptions on erosion rates and the removal of limestone topography, and by ignoring paleontological evidence for the antiquity of exposed raised limestones.

## DENSITY AND POROSITY: INFLUENCE ON REEF ACCRETION RATES

David Hopley  
 James Cook University, Townsville, QLD, Australia

Estimations of coral reef accretion rates can be undertaken using a number of techniques. Most tedious is the use of growth rates from individual organisms (Chave et al., 1972). More recent methods include the measurement of total reef metabolism and calcification (Kinsey, 1985) or estimates of rates during the Holocene from dated drill cores (Davies, 1983; Davies and Hopley, 1983).

Alkalinity anomaly measurements can be made for different zones of the reef. However, in transforming results, from kg m<sup>2</sup>/year into vertical accretion rates, differences in specific gravity (S.G.) of different elements of the reef need to be considered. Elements such as corals, molluscs, codiaceans and *Halimeda* are composed of aragonite (S.G. 2.94) while coralline algae, foraminifera and bryozoans are mainly magnesium calcite (S.G. 2.72).

Producing even greater variability in the conversion is the porosity of the reefal fabric. Coral colonies have bulk densities of 1.0–2.2 g/cm<sup>3</sup>, (Buddemeir et al., 1974). The reef fabric in drill cores has a wide range of porosities from very low (where internal cavities have been infilled with marine cements) to very high, in branching coral framework. Nonetheless, the results from drill cores are remarkably similar to those obtained from reef metabolism studies, where a porosity value of 50% is normally assumed, (Smith, 1983).

Vertical accretion rates (Figure 1) vary up to 16 m/1,000 years with the mode around 7–8 m/1,000 years obtained from both alkalinity studies and drill cores. Reef fabric porosity plays an important role in both framework and detrital deposition. Higher rates in framework are mainly from open branching corals, lower rates from head corals and algal crusts. Within detrital facies two distinct groupings occur:

- 1–9 m/1,000 years representing steady, mainly fine grained accumulation during normal stormy weather.
- Extremely high rates of 13–18 m/1,000 years from coarser more porous gravel sheets deposited during short periods of cyclonic weather.

**Density and Porosity: Influence on Reef Accretion Rates, Figure 1** Rates of vertical detrital and framework accretion throughout the Holocene based on dated cores (from Davies and Hopley, 1983; Hopley et al, 2007). Porosity of materials laid down strongly influences accretion rates and these in turn have a correlation with energy levels and location on the reef. (Courtesy of Cambridge University Press).

Changes to these figures occur through time. Greater porosity may result from bio-erosion while denser framework results from compaction and deposition of marine cements.

## DEVONIAN REEF COMPLEXES OF THE CANNING BASIN

Phillip E. Playford  
Geological Survey of Western Australia

Middle and Upper Devonian reef complexes are spectacularly exposed along the northern margin of the Canning Basin. They form rugged limestone ranges, in a belt some 350 km long and up to 50 km wide, that have become known as the “Devonian Great Barrier Reef.” (Figure 1).

The barrier-reef system formed as fringing reefs, atolls, and banks, which grew along the mountainous mainland shore of the Kimberley block and around rugged islands of Proterozoic igneous and metamorphic rocks. The maximum thickness of the Devonian rocks is estimated to be at least 2,500 m (Figure 2).

Three main facies are recognized in the reef complexes: platform, marginal slope, and basin facies. Most platforms were rimmed by rigid wave-resistant reefs. The reefal platforms stood tens to hundreds of meters above the adjacent seafloor, and were constructed by shallow-water organisms: mainly stromatoporoids, corals, and microbes

during the Givetian and Frasnian, and microbes during the Famennian (Figure 3).

The platform deposits were laid down essentially horizontally, in shallow subtidal to intertidal and supratidal environments, while the marginal-slope deposits, consisting largely of platform-derived debris, were formed on steep slopes in front of the platforms, reaching depths of up to several hundred meters. The basin facies, which was laid down essentially horizontally, consist largely of calcareous shale, siltstone, and sandstone.

The reef complexes range in age from Middle Devonian (late Givetian) to late Devonian (Frasnian and Famennian). The most precise datings are based on conodonts and ammonoids in basin and marginal-slope deposits. The platforms were retreating (retrograding) and backstepping during the Givetian to late Frasnian, and advancing (prograding) during the latest Frasnian and Famennian. This pattern may have been linked to a long-term rise and fall in global sea level. The Frasnian–Famennian boundary marks the culmination of a global mass extinction of meta-zoan organisms (Figure 4).

Third-order sequences, associated with backstepping of the platforms, are thought to be linked with episodes of faulting. The rigid early cemented reef limestones were

subjected to fissuring in response to contemporary earthquake shaking, slippage along underlying marginal-slope deposits, and differential compaction over buried basement topography. The fissures were filled with sediment,

calcite cement, and organic growths, forming networks of neptunian dykes.

The lithologies of the reef complexes have remained essentially unaltered since deposition, other than in about

had profound effects on the Devonian rocks. The tops of the limestone ranges were planed off by “dirty” ice at the base of the ice sheets and were extensively karstified by the corrosive action of subglacial water under high pressures and subzero temperatures.

### Definition

The biological, physical, and chemical processes occurring concomitantly or separately in time and modifying a sediment during and after its deposit.

### Introduction

Reefs have caused a tremendous interest in diagenetic studies in the past decades, with a particular exponential development during the 1970s and 1980s, just after the major discovery of the early submarine cements in modern coral reef complexes in the late 1960s (Ginsburg et al., 1967; Macintyre et al., 1968; Land and Goreau, 1970).

In the general topic of carbonate diagenesis, reefs represent highly favorable systems for the study of diagenetic processes because they are especially susceptible to diagenesis occurring either in marine, mixed, or nonmarine waters, and as sedimentary systems, they have relatively clearly defined geometries. Another reason explaining their scientific interest is their reservoir potential, and from this point of view also, the precise analysis of reef-limestones diagenesis is of critical importance for the assessment of their economic significance.

Independently from their age and setting, reefs present several fundamental specificities as regards carbonate diagenesis:

1. They are formed with a very high primary porosity.
2. They are lithified at their time of growth, this limiting the effects of compaction and hence permitting the preservation of initial porosity.
3. Reef facies are usually composed of chemical unstable minerals, such as aragonite and high-magnesian calcite (HMC), which can easily undergo various chemical and mineralogical changes through interaction with circulating pore fluids.

The aim of this encyclopedia is to focus on modern reefs. For this reason, the diagenetic features and processes described here are related to the early diagenesis in the sense of syndepositional diagenetic processes and do not include those depending on burial diagenesis.

### General approach and technical methods

Research in carbonate diagenesis has used, and is still using, a process-based approach, i.e., relying on the identification of processes producing the diagenetic modification, in contrast to the general analogy-based approach classically used in geology and more particularly in stratigraphy and facies studies.

While laboratory experimentation on precipitation–dissolution of the different carbonate species under strictly controlled physicochemical conditions has potentially proved to be of great help for our understanding of the mechanisms involved in carbonate diagenesis, a purely physicochemical approach alone cannot provide the keys for deciphering the highly diverse diagenetic pathways and their effects on the studied carbonate system through time and space. This is mainly due to the fact that the interior of a reef is a strongly dynamic system involving many interactions of biological, physical, and chemical processes and important movements of water masses facilitated by the high porosity and permeability typical of reef facies.

The usual approach is preliminarily based on a petrographical analysis of thin sections under the optical microscope, combined with SEM observations and geochemical characterization of the identified diagenetic products. Complementary observations and analyses involving various sets of more sophisticated techniques may be further undertaken depending on the scientific questions arising from the first results and on the specific objectives of the study concerned. The improvement and development of analytical techniques in recent years provide us with a large spectrum of potential analyses encompassing the fields from biochemistry to mineralogy.

### Cementation

#### Early cements

##### *Early cements in recent reefs*

*Aragonite cements* are frequently developed in Holocene, including present day and Pleistocene coral reefs. Two distinct types of aragonite cements are commonly recognized: the needlelike or acicular aragonite cement (Figure 1a) and the botryoidal aragonite (Figure 1b and c). The first type of cement has been frequently described in numerous studies of recent reefs and numerous terms have been used to describe the various morphologies of this cement (Ginsburg et al., 1971; Ginsburg and Schroeder, 1973; Schroeder, 1972; Bricker, 1973; James et al., 1976; Macintyre, 1977; Harris et al., 1985; James and Ginsburg, 1979). The acicular crystals are typically 2–10 µm wide and 50–300 µm long with pointed terminations, elongated parallel to the crystal's *c*-axis and having straight extinction (Aïssaoui, 1986). The morphological varieties of this cement include acicular crystals occurring as isopachous fringes, bladed crystals, fanlike needles, and needle meshworks, like those described in Belize (James and Ginsburg, 1979). The acicular cement frequently forms a relatively loose structure resulting from the sometimes irregular disposition of crystals. It can also consist of epitaxial overgrowths of aragonite substrates, usually aragonitic mollusks or coral fragments (Figure 1a). The distribution of this cement has often been shown to be very heterogeneous, even within the same thin section, with some primary voids completely filled up with this cement and the neighboring pores entirely devoid of aragonite needles.

**Diagenesis, Figure 1** Early marine and nonmarine cements, Mururoa Atoll, Holocene and Pleistocene reef facies. (a) Aragonite acicular cement forming epitaxial overgrowths on aragonite scleractinian coral skeleton, thin section, scale bar: 250  $\mu\text{m}$ . (b) Botryoidal aragonite cement overgrowing a isopachous high-magnesian calcite (HMC) fibrous cement, polished slab, scale bar: 1 cm. (c) Two botryoids of aragonite cement, thin section, crossed nichols, scale bar: 250  $\mu\text{m}$ . (d) HMC isopachous cement around fragments of coral branches, this cement is overlain by geopetal infills of marine internal sediment, polished slab, scale bar: 2 cm. (e) HMC isopachous fibrous cement followed by a thinner layer of sparitic low-magnesian calcite (LMC) cement, thin section, scale bar: 300  $\mu\text{m}$ . (f) HMC isopachous bladed palissadic cement, thin section, scale bar: 300  $\mu\text{m}$ . (g) LMC karstic brown calcite cement, the cement is affected by boring marine organisms (lower left corner of photograph) and overlain by marine bioclastic sediment, polished slab, scale bar: 2 cm. (h) Needlelike or whisker LMC calcite cement typical of calcrete pedogenetic facies, here associated to a characteristic alveolar texture, thin section, scale bar: 500  $\mu\text{m}$ .

The botryoidal aragonite cement (Figure 1b and c) was first described from Holocene sediments of the Persian Gulf (Shinn, 1969), from Bermuda cup reefs (Schroeder, 1972) and from the Holocene reef of Belize (Ginsburg and James, 1976). Pleistocene examples have also been described in details from the Red Sea, Loyalty Islands (Ouvea), and Mururoa Atoll by Aïssaoui (1985), Aïssaoui and Purser (1985), and Aïssaoui et al. (1986). The botryoidal aragonite cement forms individual and/or coalescent knolls of compact fibrous aragonite crystals with a spherulithic arrangement (Figure 1b and c). These botryoids vary in size between one to several centimeters until tens of centimeters in diameter and they have a typical translucent honey brown color in section. Petrographically, it appears that each fan of aragonite fibers presents a typical sweeping extinction under crossed nichols (Figure 1c). The individual crystals forming these fans are euhedral fibers 2–10  $\mu\text{m}$  in diameter and several hundreds of microns in length. The botryoidal aragonite cement occurs in reef open cavities, usually on the reef wall or reef slope, where it can alternate with internal marine sediment or even be affected itself by marine microborings. From the various examples described in the literature, there is no evidence of substrate control, as the aragonite botryoids were observed growing on calcite, including HMC (Figure 1b), or aragonite substrates. The Sr content of this aragonite cement is about 8,000–10,450 ppm and hence characteristic of an aragonite precipitated from normal marine waters. The composition in other trace elements and stable carbon and oxygen isotopes analyzed from the Holocene and Pleistocene botryoidal cements is also in good agreement with a precipitation from normal marine water (Ginsburg and James, 1976; Aïssaoui, 1986), although Aïssaoui (1986) described a Miocene aragonite botryoidal cement of karstic origin.

*High-magnesian calcite (HMC) cements* commonly constitute the most frequent and most volumetrically important cements in Holocene and Pleistocene reef frameworks (Figure 1d), and have been largely described in the literature. HMC cements are morphologically much more diverse than their aragonite counterparts, with morphologies ranging from fibrous and palissadic types to sparitic and micritic cements.

The fibrous HMC cements (Figure 1e) form single or several isopachous successive layers fringing primary inter- or intra-granular voids. The thickness formed by several cement layers can reach a few centimeters in some cases, such as in the Mururoa Atoll rim (Repellin, 1977; Buigues, 1982; Aïssaoui, 1986). In thin sections, they show a compact bundle arrangement, each individual bundle presenting a sweeping extinction under crossed nichols. Individual crystallites forming the bundles are not clearly distinguishable, even under the SEM. They correspond to fibers of several tens to hundreds of micrometers length, having anhedral shapes and grouped together in divergent units, several of them forming the bundle.

Bladelike forms of HMC cements or bladed spar have also been described, particularly in Belize, Mururoa, and Loyalty Islands (James and Ginsburg, 1979; Aïssaoui, 1986; Carrière, 1987). They consist of elongated crystals with angular terminations and triangular sections, which currently form palissadic layers (Figure 1f). Individual calcite crystals are typically of 20–50  $\mu\text{m}$  width for a few hundreds of microns in length. The bladed HMC type commonly occurs together with the fibrous HMC cement in the same facies and even in the same void, in addition, lateral gradation from one form to the other has already been described.

HMC sparite or stubby spar cements seem to be less common and mainly restricted to small intergranular voids in Belize and Mururoa. This cement forms isopachous fringes composed of broadly triangular crystals, a few tens to hundreds of microns large, gradually widening from the substrate upon which they grow toward the pore center. Under SEM, each calcite crystal appears composed of many thin elongated crystallites, with hardly discernible external limits. This type of cement can be considered as a variety of the bladed-spar cement.

A different blocky HMC sparite forming mosaics of equant 20–60  $\mu\text{m}$  crystals has been also described in Bermuda and Bahamas reefs (Schroeder, 1972; Pierson and Shinn, 1985) and has been also considered as precipitated from open marine waters. This cement seems, however, to be relatively rare.

HMC micrite cements are ubiquitous in most Holocene and Pleistocene reefs although its volumetric importance is highly variable from one site to the other. The magnesian micrite cement consists of small curved-face rhombs, a few microns in size, forming a thin layer about 10  $\mu\text{m}$  thick, lining surface grains. They should be distinguished from micritic envelopes resulting from the algal-microbial micritized external parts of bioclasts. As underlined by James and Ginsburg (1979), this cement seems to be, in most cases, the first to precipitate and may be followed by any other type of early cement, either calcite or aragonite. It should be noted, however, that when this cement is abundant, the questionable origin of micrite as cement precipitated from seawater or deposited lime mud, starts to be a true problem.

Their Mg content of these cements usually varies between about 10 to more than 15 mol%  $\text{MgCO}_3$ , in most of the Quaternary reefs described in the literature. In the Mururoa reef facies, there is a good correlation between the mean Mg content and the type of cement, with cements formed of fibrous or elongated crystals bearing the highest Mg content, which confirmed the effect of Mg on the development of fibrous calcite shown by the experiments of Badiozamani et al. (1977) on carbonate precipitation (Aïssaoui, 1986). The geochemical composition of HMC cements, including trace elements and stable isotopes of carbon and oxygen, is largely considered as in accordance with a marine origin.

*Low-magnesian calcite (LMC) cements* are common although usually not forming an important volume of the

limestone mass in Quaternary reefs. They are restricted to particular horizons in the reef rock and usually considered as resulting from a diagenesis related to subaerial environment. They are, therefore, linked to some degree to subaerial exposure of the reef body during emersions and, hence, can be precipitated either directly on emerged surface substrates or at depth within the reef rock in relationship with circulation of interstitial fluids. In both case, they have a nonmarine origin as shown by their low-magnesium content and their isotopic signature. The most frequent morphological types include needlelike calcite cement and a great diversity of sparite cements.

The needlelike or whisker calcite cement (Figure 1h) is developed in calcrete (caliche) pedogenetic facies and is often associated with the characteristic alveolar texture formed by networks of interconnecting micrite walls representing rhizoconcretions or rhizoliths. This calcite is composed of single fibrous crystals often forming a loose meshwork and displays a variety of habits and arrangements of individual crystals. The precise origin of this typical cement has been questioned for past decades to know if it results from direct precipitation in close relation with the high degrees of supersaturation caused by physicochemical changes in soil profile or if it has a biogenic, possibly microbial origin, and this is still a matter of debate (Goudie, 1996; Cailleau et al., 2009).

The mosaic sparite cement consists of large size (from 100  $\mu\text{m}$  to more than 1 mm) limpid crystals either with a thick and irregular shape or slightly more elongated with euhedral terminations. It fills up partially or completely primary or secondary intra- and inter-granular voids.

The elongated-crystal sparite or brown calcite cement (Figure 1g) is formed by individual elongated crystals widening toward the center of the cavity within which they develop, and having pyramidal terminations. The sometimes important development of these cements in relationship with emersion surface and karstic processes clearly demonstrate their subaerial origin, also corroborated by their trace element and isotopic composition.

#### *Early cements in ancient reefs*

Ancient reefs commonly have undergone successive steps of various diagenetic processes, including diverse phases of cementation, linked to the changing physicochemical conditions and supersaturation state in pore fluids during their geological history. As a result, in this chronology, each diagenetic phase provides new diagenetic products and affects in some degree the preexisting materials of sedimentary, biological, and diagenetic origins. While the relative chronology of cements in ancient reefs can be established from detailed petrographical analyses, their original mineralogy and geochemical composition have to be deduced through interpretation of available data.

*Botryoidal cements* in ancient reefs and carbonate platforms are relatively common and have been described from Precambrian to Cenozoic formations. While their

morphology and size are similar to their counterparts occurring in recent reefs, they differ significantly in terms of their current mineralogy and petrography. Ancient botryoidal cements are formed by LMC sparite resulting from the calcitization of the original fibrous aragonite, as shown by the frequent presence of aragonite relics included in the spar crystals (Mazzulo and Cys, 1979; Mazzulo, 1980; Aïssaoui, 1985). Diverse origins have been demonstrated for these ancient botryoidal aragonite cements.

*Fibrous cements* represent frequent syndimentary cements in ancient reefs and non-reef carbonate platforms. They usually form isopachous layers of fibrous crystals, parallel or in fanlike arrangement, in primary voids and often present a sweeping extinction when seen in thin section under crossed nichols. They are usually rich in dark micro-inclusions and depending on their diagenetic alteration, a sparitic structure can be overprinted upon the original fibrous arrangement. Most ancient fibrous cements have not preserved their original mineralogy and are formed by LMC. In the lower part of the carbonate formation in Mururoa Atoll, Berbey (1989) has shown that the early marine fibrous HMC cements have undergone a diagenesis leading to the gradual loss of their Mg content, probably by progressive Ca–Mg substitution in the calcite lattice.

*Sparite cements* are generally the most abundant cements in ancient reef facies and usually consist of LMC. Several types can be differentiated from the arrangement and morphologies of crystals and usually the relative chronology of cements can be established for petrographical analysis. However, origins of these LMC sparite cements can be highly diverse, including early diagenesis from surface waters to late burial diagenetic cementation. As there is no *a priori* reliable criterion either geochemical or petrographical, which allows surface/near-surface sparite from deep burial sparite to be distinguished, the precise origin of these cements together with the quality of their parent waters remain extremely difficult to infer, depending mainly on the degree of knowledge of the geological context.

#### **Cementation in reefs**

##### *Role of cementation*

Numerous studies have shown that rapid lithification through syndimentary marine cementation is a widespread feature common to many, if not all, modern tropical corals reefs (Macintyre, 1977; Friedman, 1998) and the development of early cements in ancient reefs is also well known. Therefore, one of the main characteristics of both recent and ancient reefs is that they are being cemented at the time of their growth.

Although the first primary actors in the reef development are undoubtedly the reef-building organisms edifying a rigid mineralized biological framework, early lithification of sediment and cementation of the framework can exert also an important role in the edification of reefs (Purser and Schroeder, 1986). This occurs at

several temporal scales (1) through the contribution of early cements to the rigidity of reef buildups and, hence, the maintenance of the positive relief above the surrounding seafloor sediments and (2) through the high preservation potential of the reef structure in the fossil record.

#### *Distribution of cements*

*At the scale of microfacies*, the variability of cements distribution both in modern and ancient reefs is well known. The distributional pattern of cements at that scale is directly dependent on (1) the amount of water present in the reef porosity and (2) the petrophysical properties (i.e., porosity and permeability) of the reef limestone, while the mineralogical and geochemical characteristics of cements are mainly controlled by the water chemistry. The control exerted by the amount of water is well explained and depends on the position of the considered site relatively to the water table, i.e., phreatic or vadose zones. This affects the amount and distribution of cement being produced: less cement restricted at the lower grain surface or at the contact between neighboring grains in the vadose zone, more cement forming isopachous fringes surrounding grains and lining primary voids in the phreatic zone. The differences in the morphology and distribution of cements occurring at fine scale, even between adjacent pores or within the same thin section, are explained by fine-scale changes in porosity and permeability, resulting notably from size and interconnectivity between voids. They are consequently extremely difficult to predict or to generalize for modeling. The concept of microenvironment, as used in diagenetic studies of reefs, has been created in an attempt to overcome this problem. The diagenetic microenvironment, defined as the fine-scale environment within which diagenetic processes are taking place, is characterized both by its chemical and petrophysical properties.

**At the scale of the reef complex.** The intense marine cementation along the seaward margins of reef complexes has been largely evidenced in a multitude of modern examples throughout the world and belonging to various types of reef settings located both in the Atlantic – Bermuda (Ginsburg et al., 1971), Belize (James and Ginsburg, 1979), South Florida (Lighty, 1985), Jamaica (Land and Moore, 1980), and Galeta Point in Panama (Macintyre, 1977) – and in the Indo-Pacific – the Great Barrier Reef (Marshall, 1986), and Mururoa Atoll and Loyalty Islands (Aïssaoui, 1986; Aïssaoui and Purser, 1985, 1986; Carrière, 1987). The distribution of syndimentary marine cementation is strongly heterogeneous at the scale of the reef complex, with intensely cemented facies on the seaward edges while the leeward and lagoonal sediments remain few or almost not cemented. This has been well illustrated both in uplifted and non-uplifted reef platforms (Aïssaoui, 1986; Carrière, 1987; Figure 2) and conceptualized through the “principle of maximal cementation” (Aïssaoui and Purser, 1985).

Nonmarine cements, related to the history of the reef platform in response to the sea-level changes and periods of emersions, show a very contrasting distribution, concentrated at particular levels following the stratigraphy and from which the importance of cementation is gradually decreasing downward in the reef limestones. This distributional pattern expresses the control of gravity on the circulation of interstitial waters from which the cements are precipitated during the low stands of sea levels (Figure 2).

#### *Controls of cementation*

**Control by substrate properties.** The properties of substrate being cemented exert undoubtedly a strong control over the characteristics of the cement itself in some cases, while there is not apparent control in others. The epitaxial overgrowths and syntaxial cement of acicular aragonite are well known to develop preferentially on substrates composed of fibrous aragonite, mainly corals and gastropods in the reef environment. In this case, both the mineralogy and ultrastructure of the substrate control the mineralogy and morphology of the cement. Less frequent examples have also been described for fibrous HMC cement developing upon fibrous calcitic biogenic substrates such as hyaline foraminifera (*Amphistegina*). In thin section, there is usually an optical continuity between the crystals of the substrate and those of the cement.

At slightly larger scale, the petrophysical properties of the substrate seem to control the morphology of HMC cements. Aïssaoui (1986) has shown that there is a good correlation between the elongated shape of cement crystals, itself influenced by the Mg/Ca ratio, and the size of the primary voids being cemented.

**Hydrodynamics.** The asymmetrical distribution of cements is explained by several factors favoring the rapid development of cements along the seaward reef margin, in particular, the higher-energy conditions and cooler oceanic water temperatures, together with the higher permeability and connected porosity of the reef-front facies compared to the fine-grained sediments of the more sheltered back reef or leeward side. The higher-energy conditions on the seaward side are driven by the effect of waves and tides. The higher hydrodynamics on that side allows a large volume of water to pass through the reef framework and an efficient CO<sub>2</sub> degassing to be produced by the warming and moving of the cool open marine waters, resulting in the rapid and significant growth of cements.

#### **Internal sediments**

The link between internal sediment and diagenesis is chronological as the internal sediment is defined as being deposited within the voids of an already lithified substrate. The internal sediment therefore occurs after the first cementation. A certain degree of hydrodynamics is

**Diagenesis, Figure 2** Schematic distribution of early marine cements (1), and nonmarine meteoric cements (2) at the scale of platform or reef complex; volcanic basement in gray. (a) Mururoa Atoll, French Polynesia; (b) The tilted half-atoll of Ouvéa, Loyalty Islands, New Caledonia; (c) The tilted platform/atoll of Maré, Loyalty Islands, New Caledonia. (Modified from Aïssaoui [1986] and Carrière [1987].)

necessary for permitting the sedimentary particles to be introduced and moved within the rock frame. From this point of view, the reefs with their good porosity and permeability, their high susceptibility of early cementation, and their high-energy environmental conditions, are excellent candidates for internal sedimentation.

#### Marine internal sediments

These represent the most frequent internal sediments in modern and ancient reefs. They are generally characterized by their fine-grained bioclastic components and their geopetal arrangement (Figure 1d).

#### Nonmarine internal sediments

These internal sediments are the products of subaerial diagenesis, either in the vadose zone or related to karstic processes during periods of sea-level low stands. Consequently, they represent important discriminant criteria in the reconstitution of reef history and its response to sea-level changes.

#### Vadose internal sediments

*Vadose silts* consist of geopetal accumulations of tiny crystalline debris, produced by the abrasion and mechanical erosion of previously lithified substrates in the meteoric vadose zone. They are frequently associated with sparitic cements and intense dissolution features related to meteoric diagenesis.

*Centrifugal micrite* is not a commonly observed feature in Holocene and Pleistocene coral reefs (Carrière, 1987; Perrin, 1989), certainly due to its narrow zone of occurrence restricted to the supratidal zone (Purser, 1973; Aïssaoui and Purser, 1983).

#### Karstic internal sediments

These internal sediments are filling either primary voids or dissolution cavities sometimes of large size. Their nonmarine origin is attested by the general lack of marine bioclasts, the presence of clays and laminated crusts of pedogenetic origin, together with their typical orange-red color. They may include rock fragments and breccia infilling the largest cavities.

## Dissolution

### Selective dissolution of skeletal elements

The susceptibility of skeletal grains to dissolution is directly related to their mineralogy, their ultrastructure, and their morphology. The bioclasts composed by the most unstable mineralogical phases, such as HMC and aragonite, are obviously the first to be dissolved. However, in details or during the early stages of dissolution, differences are shown between elements of similar mineralogy. This differential susceptibility to dissolution depends on the content in trace elements, notably the ratio Mg/Ca of high-magnesian calcitic bioclasts and on the fine-scale skeletal ultrastructure. This has been well documented for coral skeletons, ultrastructural patterns of which being taxon dependent. Hence, some coral taxa have revealed more sensitive to dissolution than others, and dissolution has been shown to occur preferentially at particular sites, such as trabecular axes and/or median septal plans (James, 1974; Gvirtzman and Friedman, 1977; Constantz, 1986; Dullo, 1986; Perrin, 2004). Additionally, the earliest steps of dissolution evidenced from still living colonies have been demonstrated to occur in the calcification centers, which are more abundant at these particular sites, just a few years after the skeleton being secreted (Perrin and Cuif, 2001). This appears to be strongly linked with the rapid decay of intraskeletal organic matrices more abundant in the centers of calcification (Perrin and Smith, 2007a, b).

### Dissolution of early cements

During the diagenetic evolution of reefs, early cements may be affected by following diagenetic processes including dissolution. Therefore, selective dissolution is not restricted to the biogenic components. Similarly, the mineralogy, morphology, and trace element composition of the cement are important factors controlling its susceptibility to dissolution. Aragonite, HMC, and, even, calcian dolomite cements are variably susceptible to dissolution (Purser and Schroeder, 1986). In the recent reefs of Mururoa and Ouvéa, dissolution of botryoidal aragonite occurs at microstructural scale forming micro-rhomboidal voids visible under SEM (Aïssaoui, 1985, 1986). Various degrees of partial dissolution have been described in the Pleistocene facies of Mururoa Atoll, affecting the isopachous fringes of fibrous high-magnesian calcitic cements (Aïssaoui et al., 1986; Aïssaoui, 1988). However, the irregular dissolution pattern observed or its preferential location at some levels within the thickness of cement layer remain difficult to explain and may be related to a differential original composition of crystals forming the cement (Aïssaoui, 1986).

### Dissolution of dolomite

The dissolution of dolomite or dedolomitization leads to the formation of typical secondary voids which may be common in Holocene, Pleistocene, or older reef rocks. These traces of dedolomitization require to be identified

from thin sections. They are characterized by geometrical voids, a few tens of microns to several millimeters in size, which do not evoke the typical shape of any known bioclast, the smaller voids having often a rhomboedral periphery as does the dolomite crystal. Relics of small crystals of calcian dolomite have been already described on the walls of such secondary voids, hence leaving no doubt regarding their origin (Aïssaoui, 1986). The secondary voids produced by the dissolution of dolomite in reef carbonates can represent a quite important proportion of the total rock, reaching in some cases 40%.

As a consequence, the significance of these dissolution voids is extremely important for the interpretation and reconstruction of reef history and the understanding of reef diagenesis, since this secondary porosity is the only evidence for an earlier stage of dolomitization. As a consequence, dolomitization events have to be characterized through petrographical observations of thin sections and not solely through mineralogical analyses such as x-ray diffractometry, for example. Moreover, the identification of dedolomitization voids may help in the precise reconstruction of the initial geometry of dolomitic bodies (Purser and Aïssaoui, 1985; Aïssaoui, 1986).

### Distribution of dissolution features in reefs

Dissolution in reefs is a ubiquitous process, which often is only detectable at the microscopic or even at the ultramicroscopic scale. The process itself starts at a very early stage, in some cases just after the formation of the carbonate features which is affected by dissolution (Perrin and Cuif, 2001; Perrin, 2004).

Larger-scale dissolution features in reefs are known to occur during sea-level low stands through the exposure of the marine carbonates to the effects of meteoric waters, this leading to the formation of karstic framework and cavities especially under prevalent humid tropical climatic conditions. These macro- to mesoscale dissolution features are distributed at specific horizontal intervals in the ancient reef carbonates and are characterized by open voids, chalky facies, and associated with other meteoric and karstic features (e.g., typical cements and infills).

### Controls of dissolution

The dissolution process is by definition selective in carbonates and this selection is operated through two main controls: the fine-scale ultrastructure and the mineralogy including the trace element composition. The ultrastructure determines the size and arrangement of individual crystals and hence, within a given structure, either biogenic or nonbiogenic, the distribution of crystal boundaries, discontinuities, and crystalline faces which are preferential sites, highly favorable to the initiation of dissolution process. This has been largely evidenced in various groups of skeletal carbonates (Walter, 1985; Dullo, 1986; Flessa and Brown, 1993; Perrin, 2004). In the case of biogenic elements, the intraskeletal organic material (proteins) and its degradation during the early stages of

diagenesis probably play a crucial role in the stability of skeletal carbonates (Perrin and Smith, 2007a, b). This is expressed by the fact that elements of same mineralogy often show various degrees of dissolution depending on the nature and origin of the structure considered: e.g., in some cases aragonite cement may be more resistant to dissolution than their aragonite skeletal substrate (e.g., Scherer, 1986).

### Dolomite in reefs

Reefs are highly susceptible to dolomitization compared to other carbonate facies, as shown by the numerous ancient, including Quaternary, reef bodies and reef platforms which are completely or partially affected by dolomitization. As already emphasized by Purser and Schroeder (1986), the high susceptibility of reefs to dolomitization is the result of a combination of favorable factors such as (1) the important primary porosity and permeability of reef facies, (2) their early history frequently dominated by sea-level changes and therefore rapid evolution of the chemistry of interstitial waters, (3) a high content in metastable minerals, and (4) the presence of organic material.

### Petrography of dolostones

Dolomite may result from different diagenetic processes comprising cementation, replacement of sedimentary or diagenetic precursors, and recrystallization of dolomitic precursors, the three processes occurring often concomitantly in reef facies (Buigues, 1982; Purser and Aïssaoui, 1985; Carrière, 1987; Berbey, 1989). The identification of these processes from petrographical analysis of thin sections permit various dolomite petrotypes to be defined and characterized from geochemical analysis, their distribution within the reef platform to be mapped, and beyond, the interpretation of diagenetic fluids, and the development of dolomitic bodies to be reconstructed.

#### Cementation

In thin section, these dolomite cements are dolosparites characterized by limpid crystals of relatively large size (a few tens to more than 100  $\mu\text{m}$ ), developed in primary and secondary voids, which they may fill completely (mosaic of cement) or partially (fringe of cement).

A quite frequent particular case corresponds to dolomite rhomboedral crystals, typically a few tens of microns, consisting usually of a central darker microcrystalline part resulting from the replacement of a non-dolomitic precursor, and a limpid border, interpreted as the further growth of the same crystalline unit within a void (cementation).

#### Replacement

The replacement dolomites include most of the microcrystalline dolomites, which preserve the detailed shape of bioclasts or previous cements, and most of their texture and consist of small rhomboedral crystals a few microns to 10  $\mu\text{m}$  in size. These replacement dolomites often show a relatively high intercrystalline porosity.

#### Recrystallization

The recrystallization dolomites are generally represented by large-sized (a few hundreds of microns) rhomboedral to subrhomboedral crystals, which often show inclusions of much smaller rhomboedral dolomite crystals. This, together with the disappearance of any textural remain of precursor suggests successive phases of recrystallization of previous dolomitic elements (Buigues, 1982; Purser and Aïssaoui, 1985). Within a given reef complex, the oldest dolomites of recrystallization have been shown to be those having the highest Mg content, this increase in Mg/Ca ratio compared to the other dolomite types may be due to a gradual equilibration toward a stoichiometric composition, characteristic of many ancient dolomites in fossil reefs (Buigues, 1982; Berbey, 1989; Koch and Shorr, 1986).

### Distribution of dolomite in reefs

The study of diagenesis in Holocene and Pleistocene reefs constitutes a major contribution to our general understanding of dolomitization of carbonate platforms because ancient platforms have generally undergone a complex diagenetic history including several phases of dolomitization including syndimentary and burial diagenetic stages.

As shown in recent Cenozoic reefs, although the different types of dolomite (cementation, replacement, and recrystallization) may occur in the same reef facies, some broad general trends have been described showing the dominance of some processes in some parts of the reef complex (Figure 3). The dolomitic cements tend to dominate the external margins of the reef complex where primary porosity is higher due to coarser facies and circulation of diagenetic fluids more efficient. By contrast, the replacement dolomites are usually better developed in the lagoonal or back-reef finer sediments while the recrystallization dolomites are more characteristic of the oldest basal parts of the dolomitic body (Buigues, 1982; Aïssaoui, 1986; Purser et al., 1994).

### Dolomitizing fluids

#### Isotopic approach

The stable isotopic composition of dolomites may reveal the marine or nonmarine signature of dolomitizing fluids providing that the studied dolomites have not undergone a too complex diagenetic history. In that sense, the partially dolomitized facies frequently occurring on the top and margins of the dolomite body under modern reef platforms have been shown to be the most informative for the understanding of the modalities of dolomitization.

Although several models of dolomitization of carbonate platform have been considered, the prevalent model for explaining the dolomitization of reefs is the "mixing zone" system or Dorag model (Badiozamani, 1973), mainly deduced from the isotopic signature of dolomites suggesting a certain mixture of marine and meteoric waters (Buigues, 1982; Purser and Aïssaoui, 1985;

**Diagenesis, Figure 3** Schematic cross-section of Mururoa Atoll, showing the distribution of the various types of dolomite. (a) dolomitic cement dominant and (b) replacement dolomite dominant. (Modified from Purser et al. [1994].)

Aïssaoui et al., 1986; Buddemeier and Oberdorfer, 1986; Carrière, 1987).

#### *Petrographical and geological approach*

Although the petrographical and geochemical characteristics of dolomites in Quaternary reefs are known to be highly variable, the change from a calcium carbonate to a mixed Ca–Mg carbonate required a source of Mg ions, which is reasonably regarded as provided by the marine water. On the other hand, the fact that marine waters alone cannot produce massive dolomitization of the reef complex is evidenced by two basic petrographical observations: (1) the dolomitization is often associated with previous dissolution features linked to meteoric waters and (2) the most external parts of modern reef platform is not dolomitized (Aïssaoui, 1986).

#### **Diagenetic alteration – crystalline modifications** **Calcitization of aragonite**

The recrystallization from aragonite to calcite may concern either aragonite cements (Sandberg, 1984; Aïssaoui, 1985) or biogenic aragonites (James, 1974; Pingitore, 1976; Gvirtzman and Friedman, 1977; Sandberg, 1984; Dullo, 1986). In both cases, the transformation involves at very small scale, a prior discrete dissolution process of the aragonite precursor, followed by a precipitation of calcite within the newly created secondary voids, both processes may occur concomitantly at very short distances (a few microns to tens of microns) from each other. The overall transformation operates as a migrating front of dissolution–precipitation. While this appears obvious in the case of aragonite cement, in some biogenic aragonite the transformation may be further controlled by the textural and compositional differences of the skeletal structures, making hence the recognition of a geometrically simple front of dissolution–precipitation difficult.

These concomitant discrete processes of dissolution–precipitation strongly differ from the transformation at solid state characteristic of metamorphic conditions.

#### **Transformation of HMC to LMC**

In the cored material from Mururoa Atoll, several types of magnesian calcite cements having different Mg values

have been described (Aïssaoui and Purser, 1985; Aïssaoui, 1986). The type 2 cement has variable Mg values, always equal or lower than the type 1 cement. The type 2 cement has been interpreted as resulting from the gradual diagenetic transformation of the early marine fibrous HMC cement (Aïssaoui and Purser, 1985). In the deeper parts of the atoll rim, the early fibrous or radial calcite cements have even lower Mg values (less than 3% mol  $\text{MgCO}_3$ ) (Berbey, 1989). This gradual change of Mg content likely results from diagenetic processes involving partial micro-dissolution of HMC, as suggested by Berbey (1989), and/or Ca–Mg substitution in the calcite lattice.

#### **Dolomitization**

Dolomitization may affect either bioclots, or sediment, or early diagenetic cements, in particular HMC cements. Dolomite can replace calcite or aragonite precursors. The gradual development of dolomite to the detriment of the calcite or aragonite occurs through a migrating front of dissolution–precipitation leading to a progressive digestion of the calcite or aragonite precursor by dolomite (Gebelin et al., 1980; Aïssaoui, 1986).

#### **Skeletal diagenesis**

Skeletal carbonates, including those occurring in reef facies, are known to be highly susceptible to diagenesis and often undergo rapid and discrete diagenetic changes at a very early stage either postmortem or even already during the life of the organism. These first steps of diagenesis in skeletal carbonates are represented by discrete textural changes, micro-dissolution features and isomineral recrystallization. They have been evidenced both within biogenic aragonite (Macintyre and Reid, 1995; Perrin and Cuif, 2001; Perrin, 2004) and magnesian calcite skeletons (Macintyre and Reid, 1998; Reid and Macintyre, 1998; Hover et al., 2001). These rapid changes are strongly favored by two main features: the early degradation of intraskeletal organic matrix and the micronic size of individual biocrystals (Robbins and Ostrom, 1995; Perrin and Smith, 2007b).

## Models of reef diagenesis

Within the reef masses, hydrodynamic movements and biological activities are determinant factors controlling in various degrees and at different scales the physicochemical conditions in which diagenetic processes are operating.

### Early marine cementation

One of the most important mechanisms causing the active preferential lithification of external reef margins is the strong hydrodynamics able to displace large volumes of seawater through the reef framework from the external reef flanks to the internal zones, and hence providing significant inputs of dissolved calcium carbonate. Additionally, the textural properties of reef sediments typical from these environments, principally represented by grain-supported facies with high porosity and permeability, also favor the circulation of oceanic water through the reef mass.

The development of marine cementation is independent of climate and of the type of reef complex. As a consequence, the fact that marine cementation is more developed along the reef margin has been recognized in numerous modern reef platforms, islands, and atolls and has been also frequently observed in many fossil examples (Figure 4). This has been nicely summarized as the “principle of maximal cementation” by Aïssaoui and Purser (1985, 1986).

### Meteoric cementation

Meteoric cements in reefs are mainly dependent on two driving factors: (1) the emerged relief, which determines the extension and thickness of sediments susceptible to be affected by cementation and (2) the regional climate, which may favor the solution of important amounts of calcium carbonate and hence participates indirectly in the oversaturation of waters responsible for cement precipitation (Figure 4).

During this meteoric diagenesis, dissolution occurs contemporaneously with cementation through flooding of interstitial fluids. Therefore, the precise delimitation of the volume within which meteoric cementation takes place is difficult to determine. However, at the scale of platform or reef complex, the meteoric cementation tends to be better developed in the central/internal parts of the platform and to affect stratiform volumes (Aïssaoui and Purser, 1986; Carrière, 1987; Perrin, 1990).

### Dolomitization

In most recent and many ancient reefs, the presence of a mixing zone developed during sea-level low stands is invoked for explaining the formation of dolomititic body in reef platform. The mixing nature of dolomitizing fluids is deduced from the isotopic composition of dolomites, their trace elements content, and their petrographical patterns.

However, the presence of a mixing zone implies that the carbonate buildup was an emerged island with

**Diagenesis, Figure 4** Models of reef diagenesis with different types of reef history: (1) early marine cementation, (2) postdepositional meteoric cementation, and (3) mixing zone dolomitization. (a) subtidal reef complex, (b) emerged reef complex with low relief, (c) emerged reef complex with high relief. (From Aïssaoui [1986].)

a freshwater lense having a significant thickness at the time of dolomitization. Moreover, a centripetal movement of oceanic waters from the external reef margin to the internal parts of the platform is required to explain the supply of Mg from the ocean to the mixing zone and the genesis of the dolomite body. The preferential distribution of dolosparite cement, compared to the replacement and recrystallization forms of dolomite, in the facies from the external parts of the reef also corroborates this view of centripetal displacement of waters through the reef volume.

Several mechanisms may act independently or together responsible for producing this centripetal water movement. These are (1) the natural movements of oceanic waters such as waves, tidal currents, and storm waves; (2) thermal convection generated by the difference of water temperature between the internal parts of the platform and the ocean (Rougerie and Wauthy, 1986; Rougerie, 1995); and (3) at a larger timescale, eustatic fluctuations also produce lateral water movements.

The genesis of a dolomititic body in a reef complex is directly linked to three main conditions (Figure 4):

1. The presence of a mixing zone between marine and nonmarine waters.

2. An active hydrodynamics generating a centripetal displacement of oceanic water, which passes through the reef mass.
3. The presence of an aquifer of a minimal size necessary for the development of a significant dolomitic body. This supposes a relatively important relief above sea level or surface area of the emerged island (Aïssaoui, 1986).

### Outlook: What we still do not know about reef diagenesis

The diagenetic modification of a carbonate sediment results from cumulative effects of numerous biological, physical, and chemical processes acting independently and successively in time or interacting concomitantly. The diversity of processes involved and the way they may interact with each other leave in our present understanding of carbonate diagenesis several, if not many, important gaps and question marks, some of which are listed and briefly discussed below, but the list is far from being exhaustive.

### Role of organic matter

The interactions between organic matter and carbonate precipitation or dissolution have been invoked in numerous works on carbonate diagenesis, including reefs, since the beginning of studies of diagenesis in carbonate platforms. In particular, the influence of organic compounds is frequently considered as the potential cause of the non-thermodynamic behavior of carbonates (Morse et al., 2007).

The assessment of the complex and diverse interplays between carbonate mineral and living, dissolved or amorphous organic material has made significant progress in the past 2 decades, but is still in its infancy. Both *in vitro* experimentation and *in situ* observation-based research in natural environments are needed in order to improve our understanding of such systems.

Three different categories of interactions, which are potentially of tremendous importance for diagenesis, may be distinguished: (1) the behavior of carbonates (and related diagenetic processes) in the presence of dissolved organic matter, (2) the relationships between organic compounds and mineral surfaces via adsorption at preferential sites, and (3) the presence of glycoproteinous material as intraskeletal organic matrices within skeletal carbonates and bioclasts.

### Role of microbial processes in reef diagenesis

In recent years, research investigations on living coral reefs have been focused on the qualitative and quantitative assessment of microbial benthic communities, including photosynthetic microphytobenthos. This notably revealed that the contribution of these microbial associations to the primary carbonate production of the entire reef ecosystem may be in the same order of magnitude of the production estimated for corals (Werner et al., 2008). The potential

role of these microbes on the processes of early diagenesis, especially marine cementation, has to be investigated together with the general understanding of possible interactions between single microbes, biofilms, and mineral surfaces in marine and nonmarine interstitial waters.

Inversely, the role that early diagenesis can play in the preservation of these biofilms and traces of microbial assemblages in recent and deep geological record appears particularly complex and represents a still open field for future research.

As far as reefs and carbonate platforms are concerned, these two points have strong and direct links with the practical highly relevant questions of the origin and interpretation of peloids (their nature as cement, internal sediment, or microbialite) and the general lack of discriminant criteria for inferring the nature of micritic crusts in general.

## DOLOMITIZATION

Peter Flood

University of New England, Armidale, NSW, Australia

### Definition

Dolomite,  $\text{CaCO}_3 \cdot \text{MgCO}_3$ , is a common *mineral*, usually found with limestone ( $\text{CaCO}_3$ ). The *rock*, consisting principally of the mineral dolomite, is also called dolomite; more recently it has come to be called dolostone. The process of the formation of the mineral and rock is referred to as dolomitization.

### Dolomite, the mineral, and the dolomitization process

Dolomite, the mineral, was named at the end of the eighteenth century by the French Naturalist/Geologist Deodat Gratel de Dolomieu (1750–1801) for rocks in the Southern Tyrol Alps of northern Italy, an area now referred to as the Dolomites. The study of the formation of dolomite commenced with the classic papers of Cullis (1904), Skeats (1905) and Van Tuyl (1916). The reader is referred to Deelman (2008) for a comprehensive discussion on its mineralogy, regional occurrences, mechanisms of formation, and the subtleties of its chemistry including ordered/disordered and stoichiometric/enriched dolomites. Dolomite is not a solid solution series with Ca and Mg end members but a mixed lattice crystal, which contains approximately equal amounts of  $\text{CaCO}_3$  and  $\text{MgCO}_3$ . The  $\text{Ca}^{2+}$  and the  $\text{Mg}^{2+}$  ions are separated into individual monolayers, which are themselves separated by carbonate ion layers. Simple substitution of calcium ions by magnesium ions is not possible and non-stoichiometry is very common. Usually, the wt%  $\text{CaO}$ :wt%  $\text{MgO}$  = 3:2. This is a very important factor to be considered in the models of dolomitization, for simple substitution of  $\text{Ca}^{2+}$  ions by  $\text{Mg}^{2+}$  ions is not chemically feasible and dolomitization models that propose this process are in error. Notwithstanding this, seawater is an ideal source of the  $\text{Mg}^{2+}$  ions for dolomitization in reefal carbonates. Nucleation of dolomite cannot be explained in terms of classical equilibrium thermodynamics. Deelman (2008) proposes that reaction kinetics that provide ongoing multiple fluctuations better explain dolomite formation. "The kinetic hindrances to dolomite precipitation from seawater can be overcome by evaporating seawater, diluting it, raising the temperature or lowering the  $\text{SO}_4^{2-}$  content" (Tucker and Wright, 1990). These authors as well as Deelman (2008) provide a comprehensive, up-to-date account of the complexities of dolomite formation, either as a primary precipitate or as a secondary replacement of a metastable precursor mineral. It was Deelman (1999) who first explained how dolomite can form under low temperatures and atmospheric conditions through

alternating conditions of dissolution and precipitation whereby metastable precursor minerals, such as magnesium calcite, change to more stable phases such as dolomite. Such conditions require large-scale fluctuations in pH, which is controlled by the  $p\text{CO}_2$ . Deelman has explained how “breaking Ostwald’s Rule,” which governs the course of irreversible geochemical reactions, can occur when fluctuations of sufficient amplitude, frequency, and duration are capable of crossing the border between metastable and stable fields, and both metastable and stable phases will nucleate simultaneously. During these fluctuations, conditions opposing the subsequent growth of the metastable phase will favor continued growth of the stable phase. This explanation gets around one aspect of the Dolomite Problem (Fairbridge, 1957; Hsu, 1966; Land, 1985, 1998; Hardie, 1987; Fowles, 1991; Braithwaite, 1991), which centers around the observation that dolomite will not precipitate from normal or oversaturated solutions at low temperature and atmospheric pressure. The second part of the paradox is that dolomite is a very common carbonate mineral in sedimentary rocks throughout the geological record, which contrasts with the relatively limited amount of modern day surface dolomite (see Wright and Wacey, 2004). Clearly, there has to be a simple explanation of the process of dolomitization.

Vasconcelos et al. (1995), Vasconcelos and McKenzie (1997), and McKenzie and Vasconcelos (2009) have proposed that microbial mediation may overcome the thermodynamic and kinetic barriers to dolomite nucleation in the natural environment. Anaerobic bacteria can play a role in primary dolomite precipitation and secondary replacement (Warthmann et al., 2000). Clearly, the presence of microbes is the indispensable component driving the reaction.

### Dolomite occurrences and hydrological processes

Deelman (2008, Chapter 4) provides a comprehensive account of the regional occurrences of Recent dolomites. In addition to the occurrences in coral reefs, atolls, and guyots which are discussed later, dolomite is forming in the Coorong region of South Australia, in deep sea sediments with high organic content (organogenic dolomite), in the carbonate platforms of the Bahamas, in the hot arid sabkha environments, especially, in the Middle East and in the supersaturated saline lagoons along the Rio de Janeiro coast of Brazil, namely, Lagoa Vermelha and Brejo do Espinho. Clearly all these environments, irrespective of their unique hydrological circumstances, are characterized by physiochemical conditions that fluctuate “wildly” in the presence of enhanced microbial activity. The hydrological setting in which dolomite is known to be forming have been summarized into the following: seepage reflux, capillary concentration, evaporative pumping or sabkha, solution cannibalization, groundwater-seawater mixing, Dorag dolomitization, geothermal springs, storm

recharge, Kohout convection, tidal pumping, coastal zone mixing, and evaporative mixed water. In all of these settings, seawater in some form of modification flows through the sediments or sedimentary rocks allowing for both primary deposition and replacement of preexisting carbonate particles. Often the resultant dolostone preserves the original depositional textures and “ghosts” of preexisting grains. Tucker and Wright (1991) provide a comprehensive account with numerous illustrations of these hydrological settings where dolomite is forming present day.

### Dolomite in reefs, atolls, and guyots

Montaggioni and Braithwaite (2009) provide a very useful summary of the occurrence of dolomite in Quaternary coral reef. The best data on dolomitization comes from the deep drillings of the Pacific and Indonesian atolls, especially, Enewetak, Mururoa, and Midway, all of these having been drilled more than once to pre-reefal basement.

The earliest account of the occurrence of dolomite in coral reefs is that of Skeats (1903) and Cullis (1904) in the cores recovered from the 1896 drilling undertaken by the Royal Society of London at Funafuti Atoll. Here, dolomite crystals were only detected at depths greater than 194 m where dolomite became the predominant carbonate mineral. Other drillings of Pacific Atolls (Skeats, 1905) also recorded the occurrence or the absence of dolomite (Deelman, 2008). Of particular significance were the drillings at Niue (Wheeler and Aharon, 1997; Aharon et al., 1987), Kita-daito-jima (Suzuki et al., 2005), Bikini (Ladd et al., 1948), Enewetak (Saller, 1984), Midway (Ladd et al., 1970), Mururoa and Fangataufa (Aissaoui et al., 1986; Aissaoui, 1988).

Fairbridge (1950) commented on the fact that drillings at Bikini, Maratoca (Indonesia), and the Great Barrier Reef bores of Michaelmas Cay and Heron Island did not encounter dolomite. He inferred that anoxic conditions were not present to facilitate dolomitization. More recent drillings of the Guyots of the Mid-Pacific Mountains and western Pacific have recorded the occurrence of dolomite (Flood, 1998). Recent drilling of Boulder Reef and Ribbon Reef No. 5 of the Great Barrier Reef (International Consortium for Great Barrier Reef Drilling, 2001; Webster and Davies, 2003; Braithwaite et al., 2004) failed to record the presence of dolomite, whereas deep drillings on the Queensland Continental Slope (Swart, 1993) did record the presence of dolomite.

In the Enewetak Atoll bore, Ladd et al. (1953) could not discern any pattern in the distribution of dolomite. It only occurred at depths below 1,340 m, whereas in the Kita-daito-jima bore dolomite was found only in the upper 122 m. On Midway Atoll, dolomite was found between 130 and 150 m depth. This variability in depth of the dolomite occurrences would suggest that there is no relationship between dolomite formation and water depth. Schlanger (1963) reexamined the cores from the atolls of

Funifuti, Kita-daito-jima, and Enewetak and made several deductions concerning dolomite formation. Clearly, dolomite formation was not a function of depth. No relationship between its occurrence and duration of immersion in seawater could be established. There was no obvious relationship between the presence of porosity and the occurrence of dolomite. He stated that "each atoll displays a unique pattern of distribution of dolomite." In the borings at Mururoa Atoll, Aissaoui et al. (1986) have demonstrated an extensive thickness of dolomite where the dolomite attains maximum thickness at the periphery of the atoll and thins toward the former volcanic edifice (Bardintzell et al., 1985). Trichet et al. (1984) have described in great detail the dolomite occurrences and the hydrological model responsible for the dolomitization which essentially involves dissolution – precipitation processes (Aissaoui et al., 1986; Aissaoui, 1988). The dolomite occurrences at Niue have been comprehensively documented by Aharon et al. (1987) and Wheeler and Aharon (1997) who report that the dolomite is "generally limited to two vertically distinct units which are separated by a 120 m thick interval of undolomitized limestone." They proposed that in the upper dolomite layer tidal pumping through the more permeable layers could have produced the tabular bodies of dolomite, whereas in the lower dolomite unit it is more likely to have been produced from ocean-derived saline groundwater flow and reheating.

In Resolution, Wodejebato and MIT guyots of the northern and northwestern Pacific Ocean where drilling was conducted in 1992 (Ocean Drilling Program, Legs 143 and 144) dolomite was recorded at considerable depth in excess of 2,000 m (Flood, 1998; Flood and Chivas, 1995; Flood et al., 1996). In hole ODP 866A on Resolution Guyot, the dolomite rock preserves the original depositional texture and also exhibits ghosts of the preexisting carbonate grains. The isotopic composition of the dolomite display oxygen, carbon, and strontium values indicative of precipitation from slightly modified seawaters. Here two distinct dolostone units occur; one is brown in color with a sugar-like texture, and the other is white with a massive crystalline appearance. The former appears to have formed slightly after deposition of the carbonate sediments whereas the second pulse of dolomitization responsible for the massive white dolomite occurred some 100 million years after the depositional age of the enclosing carbonates.

There are many other reported occurrences of dolomite in reefs, but they are too many to record herein. However, some will be mentioned to direct the reader to the extensive literature. They are Mitchell et al. (1987), who have described modern marine dolomite cement in a north Jamaican fringing reef; Strasser and Strohmenger, (1997) who have described dolomite occurrences in the Pleistocene reefs of the Southern Sinai, Egypt; Shinn et al. (1965) and Vahrenkamp and Swart (1994), who have reported upon Recent supratidal dolomite from Andros Island, Bahamas; and Bourrouilh (1973), Chevalier

(1973), and Coudray (1971), who have described dolomite in modern reef environments in New Caledonia.

## Summary

Dolomite,  $\text{CaCO}_3 \cdot \text{MgCO}_3$ , is a mineral commonly found with limestone and carbonate sediments of coral reefs. Dolomite does not precipitate from normal seawater or solutions at low temperature and atmospheric pressure, yet it is a very common carbonate mineral in sedimentary rocks throughout the geological record. This paradox is referred to as the Dolomite problem. Dolomite is not a product of a  $\text{CaCO}_3$ - $\text{MgCO}_3$  solid solution series but it is a mixed lattice crystal whose nucleation cannot be explained in terms of classical (equilibrium) thermodynamics where Ostwald's step rule governs the course of irreversible geochemical reactions. It was as recently as 1999 that Deelman suggested that Ostwald's Rule can be broken when fluctuations of sufficient amplitude, frequency, and duration occur and they involve changes in pH conditions related to variable  $\text{pCO}_2$ . Under such conditions a metastable precursor to dolomite (such as magnesium calcite) forms and through repeated alternations of dissolution and precipitation, change to more stable phases (such as magnesite or dolomite). He proposes that such fluctuations allow for both the metastable and stable phases to nucleate simultaneously and that during such fluctuations, conditions opposing the subsequent growth of the metastable phase will favor continued growth of the stable phase. It has recently been suggested by other researchers that the presence of microbial mediation could overcome the thermodynamic and kinetic barriers to dolomite nucleation in the natural environment.

The majority of hydrological settings in which dolomite is known to occur involve special conditions which are characteristically highly variable and fluctuating and are dominated by enhancement of fluid flow, usually of modified seawater through preexisting carbonate sediments and sedimentary rocks, especially coral reefs.

The occurrences of dolomite in Modern coral reefs and atolls has been known for over 100 years, yet the process of dolomite nucleation has evaded adequate chemical explanation until 1999 when Deelman proposed a way that it could happen. The deep borings of the Pacific Ocean Atolls and Guyots have provided a window to view the occurrence of dolomite and the processes of its formation. Of special significance have been the results of scientific investigation at Funafuti Atoll, Enewetak Atoll, Midway Atoll, Niue, Kita-daito-jima Atoll, Mururoa Atoll, Fangataufa Atoll, Christmas Island and Resolution Guyot, Wodejebato Guyot, and MIT Guyot. Equally important have been those deep borings where dolomite was not reported. They include the Great Barrier Reef, Bikini Atoll, Makatea Island, Guam Island, to name just a few. No discernable pattern of dolomite occurrence could be established. The overarching dolomitization

process in all the hydrological models involves seawater, somehow modified, and dissolution – precipitation associated with repeated fluctuations such as tidal pumping, wave action, deep ocean currents, sea-level oscillations, pulses of thermally elevated water flow, etc. The process of dolomite formation may be penecontemporaneous with sedimentation but it is more frequently postdepositional, even diagenetic. Sometimes, there can be a considerable time delay of the order of 100 m.a. between sedimentation and dolomite formation.

The more recent realization that anaerobic bacteria can play a role in the primary precipitation of dolomite is an avenue for fruitful research in addressing the topic of dolomite formation and occurrence.

## DOUBLE AND TRIPLE REEF FRONTS

---

David Hopley

James Cook University, Townsville, QLD, Australia

## Definition

The reef front is the windward margin of a coral reef with multiple fronts produced by narrower and younger sections of reef flat to windward of the main front.

The windward side of most reefs is formed by a straight edge or “hard line.” Occasionally, however, there may be a second or third line of reefs separated from the main reef by linear lagoons up to 300 m wide and 10–30 m deep. Such features have been described in New Caledonia (Guilcher, 1965; Chevalier, 1973; Battistini et al., 1975), Mayotte (Battistini et al., 1975), and Australia’s Great Barrier Reef (Hopley et al., 2007). It is suspected that other reefs, especially shelf reef systems may contain similar features.

Where double barriers occur, the outer reef invariably appears younger and may be still slightly submerged (see for example the double barrier of S.E. New Caledonia shown in Figure 5, Battistini et al., 1975). This has resulted in the suggestion that the outer barrier(s) grew from deeper foundations possibly added to the reef front as terraces during the last glacial interstadials or the Holocene transgression. The examples of the Great Barrier Reef suggest that such terraces are typically at 20–30 m depth while the Pleistocene reef to which they are attached is only 10–15 m below modern sea level. Contrasting rates of growth may have resulted: the reef growing from the terrace lagging behind sea level rises as a “catch up” reef while the main reef growing from the more extensive Pleistocene foundations would have adopted a “keep up” strategy, the result leading to a mature reef (crescentic, lagoonal) and an immature secondary reef front.

The double reef front on Gable Reef (20° 48' S) (Figure 1) has been examined in detail (Hopley et al., 2007, Figure 8.13). This Great Barrier Reef site is on the windward south-eastern rim with the secondary rim stretching partly across a wide embayment. The depth of

**Double and Triple Reef Fronts, Figure 1** The massive second front on Gable Reef overlying a reef front barrier or spit deposited during the Holocene transgression (see Hopley et al., 2007 Figure 8.13). Dating suggests that the main reef adopted a “keep up” mode during the Holocene transgression reaching modern sea level about 6 ka while the second front was a “catch up” reef 500–600 years behind its main counterpart. (courtesy Cambridge University Press)

the intervening lagoon is 20–25 m. One hole drilled into the outer rim reached 30 m but did not penetrate the Pleistocene. However, seismic survey suggested that it was 25–30 m beneath the lagoon and second front and ca. 20 m beneath the main reef. Surprisingly, the double front may not be a classic example as drilling showed that below ca. 12 m it was mainly sand suggesting that the foundations were provided by a sand barrier or spit across the embayment, as also suggested by the morphology.

Gable Reef’s main reef flat has an age of 6–5 ka, while the age of the secondary reef flat is <1.3 ka. However, only 5 m below the surface it is >5.5 ka and appears to have lagged behind the main rim by only 500–600 years. Although more complex than double fronts growing from reef terraces, the Gable Reef example does provide insight into the growth rates and age relationships of similar features elsewhere.

## EARTHQUAKES AND EMERGENCE OR SUBMERGENCE OF CORAL REEFS

---

Frederick W. Taylor  
John A. and Katherine G. Jackson School of Geosciences,  
University of Texas at Austin, Austin, TX, USA

### Synonyms

Coseismic displacement of coral reefs; Coseismic emergence or submergence of coral reefs

### Definition

Earthquakes and emergence or submergence of coral reefs: refers to vertical tectonic displacement of coral reefs associated with an earthquake. Coseismic vertical motion may cause submergence or raise the shallow part of reefs to levels relative to sea level above where they can live. The amount of vertical motion may be barely detectable or can exceed 10 m. Subsidence is less obvious than uplift, but both provide significant information regarding earthquakes and tectonic processes.

### Introduction

Early geologists realized that crustal uplift and subsidence as well as sea-level changes helped to create atolls and barrier reefs and emplace fossil coral reefs at elevations from slightly above to hundreds of meters above sea level (e.g., Darwin, 1842; Guppy, 1887; Dana, 1890). However, the relationship to earthquakes, and the causes, frequency, rates, and amounts of vertical movement for each event were matters of conjecture until examples of coseismic reef uplift were described in scientific reports (e.g., Figure 1; Taylor et al., 2008). Today, we know that both coseismic and aseismic mechanisms cause vertical displacement, but coseismic movement is nearly

instantaneous and much more dramatic. In extreme cases, uplift may be as great as ~20 m. Coseismic uplift is generally easier to recognize and document than subsidence because it causes emergence and mortality of coral and other organisms raised higher than their highest level of survival (HLS) (Taylor et al., 1987).

Coseismic reef uplift and subsidence have been documented in two geologic settings: (1) Near volcanoes along plate boundaries or intraplate hot spots where processes such as magma chamber inflation induce motion on faults, earthquakes, and vertical motion (e.g., Newhall and Dzurizin, 1988; Kaizuka, 1992; Geist et al., 1994; Amelung et al., 2000) and (2) compressional tectonic settings along plate boundaries where vertical surface displacement commonly accompanies fault rupture. Emerged coral reefs also occur on restraining bends along the trace of strike-slip plate boundaries as along the North American-Caribbean plate boundary zone in Haiti (e.g., Dodge et al., 1983; Mann et al., 1995). Just before final submission of this manuscript significant reef uplift associated with a January 2010 earthquake along a strike-slip fault in southern Haiti has been reported (personal communication, Roger Bilham). This may be the first documented case of coseismic reef uplift along a strike-slip fault system.

Today, coral reef emergence and submergence often are measured and used to investigate aspects of the subduction process. The vertical displacements of coral reefs record the amounts and distribution of elastic strain accumulation and its release as coseismic and aseismic slip. Measurements of vertical motions provide direct information about the mechanical processes accompanying volcanism and fault slip.

### Mysterious origin of emerged and submerged coral reefs

Geologists have long been intrigued by the mysterious origins of atolls and emerged coral reefs and debated the

**Earthquakes and Emergence or Submergence of Coral Reefs, Figure 1** *Porites* sp. coral heads along the southern coast of Ranongga Island, Western Solomon Islands, were killed by up to ~2.46 m of uplift associated with a  $M_w$  8.1 earthquake on 1 April 2007. Systematic measurements documented the geographic extent and amounts of uplift and subsidence (Taylor et al., 2008).

**Earthquakes and Emergence or Submergence of Coral Reefs, Figure 2** The mark pointed to by the seismological observer Bobby Kelly was emplaced by H.B. Guppy on 11 October 1882 on Uki-ni-Masi Island, Solomon Islands, to be used as a reference mark in case of future vertical displacement (Guppy, 1887).

causes for the large changes in relative sea level implied by their observations. Charles Darwin experienced an earthquake that caused coseismic uplift along the coast of Chile (Darwin, 1909, p. 314) and understood that coseismic vertical motions could cause coral reef emergence and submergence as well. Darwin summarized reports of emerged reefs, the likelihood that some uplift was recent, and the probable relationship of uplift to earthquakes (Darwin, 1842). However, he cited no confirmed evidence of coseismic reef uplift or subsidence. After visiting the Solomon Islands, Guppy (1887, p. 126) stated that “The different stages in the upheaval of several of the calcareous islands are clearly shown in the ledges or terraces displayed in their profiles. Such ledges indicate long intervals or pauses in the movement of elevation, during which the coral reefs by their outward extension formed reef flats, which have ultimately been to some degree preserved in the existing ledges, now raised to elevations often of some hundreds of feet above the sea.” However, based on his observations of apparently very young emerged reefs and bio-erosion notches in the Solomon Islands, Guppy (1887, p. 128) concluded that “. . . the protracted elevatory movements of one or two hundred feet and over have consisted in a succession of small upheavals of perhaps not more than five or six feet at a time.” To provide a basis for future measurements of vertical change he emplaced “datum” marks at several locations in the Solomon Islands. One of his marks on Uki-ni-Masi Island was located 5 ft. above high-water spring tide on 11 October 1882. During a visit on 29 July 1986, we found the mark at 5 ft 5 in. above high tide of that day and thus of no discernible difference in elevation than when installed by Guppy (Figure 2).

The earliest credible accounts of coseismic reef uplift came from missionaries and administrators and generally contain virtually no geological description or mention of uplifted corals. An example is the reported ~6 m volcanogenic coseismic uplift of a reef near Yasur Volcano on Tanna Island, New Hebrides (now Vanuatu) on 10 January 1878 followed by a few meters more uplift about a month later (Lawrie, 1898). Another account indicates that the second uplift occurred ten years after the first (Mawson, 1905). Both reports were based on second-hand accounts from missionaries. Another second-hand report of coseismic reef vertical movements comes from San Cristobal Island (Makira Island), Solomon Islands, associated with a large earthquake sequence in October 1931 (Gold, 1932; Grover, 1958). However, again these reports provided no details regarding amounts of reef emergence or subsidence and no more than a vague indication of its geographic extent.

### Scientific reports of coseismically displaced coral reefs

Perhaps the earliest first-hand scientific report described coral uplift on Malakula Island, Vanuatu, associated with a  $M_w$  ~7.7 subduction zone earthquake on 11 August 1965 (Benoit and Dubois, 1971), but the authors visited

the site several years after the event. Later, Taylor et al. (1980, 1987) mapped the uplift with hundreds of systematic measurements of emerged corals and used the data to analyze seismic slip. Maximum uplift for the 1965 event as measured in 1976 was  $\sim 1.2$  m. Additional coseismic uplift of Northern Malakula reefs occurred in association with a July 1994 earthquake south of Malakula Island (Calmant et al., 1999). Also, Pelletier et al. (2000) measured uplift of Ambrym Island, Vanuatu, near a back-arc reverse-fault earthquake in 1999.

In some cases, maximum coseismic reef uplift or subsidence may be only a few centimeters or less, as discovered by Pandolfi et al. (1994) following a May 1992  $M \sim 7.2$  earthquake along the northeast coast of Papua New Guinea. Other scientific reports of coseismic reef uplift include the Caribbean coast of Costa Rica (Plafker and Ward, 1992) and the Solomon Islands (Taylor et al., 2008). However, the most spectacular reports of coseismic reef uplift are for the great  $M_w \sim 9.1$  26 December 2004 Sumatra-Andaman earthquake that ruptured from northern Sumatra northward past the Andaman and Nicobar Islands producing uplift up to 1.5 m on some islands (Bilham et al., 2005; Meltzner et al., 2006; Rajendran et al., 2007). Subsequently on 28 March 2005, an adjacent area of the forearc ruptured beneath Nias Island causing uplift as great as 3 m, but over a smaller area (Briggs et al., 2006).

Informed by the historical reports of volcanogenic coseismic uplifts near Yasur Volcano (Lawrie, 1898; Mawson, 1905) on Tanna Island, Vanuatu, Chen et al. (1995) measured a combined uplift of  $\sim 20$  m based on well-preserved branching corals and heads on the forest floor. Uranium-series and radiocarbon dating confirmed that the corals died  $\sim 1878$  A.D. and documented several previous uplifts that sum to  $\sim 160$  m cumulatively over the past  $\sim 1,100$  years, possibly related to magma chamber inflation. Most if not all of this uplift was confined to the Yenkahe horst area and is not detectable elsewhere on Tanna Island.

Earthquakes may have accompanied uplift of coastal volcanic Mount Suribachi on Iwo Jima (Newhall et al., 1998) and  $\sim 6$  m of 1954 uplift of Urvina Bay, on the volcanic Isabela Island, Galapagos (Couffer, 1956; Colgan and Malmquist, 1987) may have been accompanied by earthquakes. A  $M \sim 6.5$  earthquake occurred on 4 June 1954 near Urvina Bay (Geist et al., 1994). Even apparently aseismic uplift of volcanic islands is often accompanied by at least small earthquakes as at Iwo Jima (Ukawa et al., 1998).

### Scientific significance of coseismically emerged coral reefs

Measurements of the amount and geography of coastal uplift and subsidence associated with the great 1960 Chile and 1964 Alaska earthquakes (e.g., Plafker, 1965; Plafker and Savage, 1970) demonstrated that vertical displacement could provide critical information about subduction processes at convergent plate boundaries. Subsequently, several coseismic reef uplifts have been used to investigate the physical parameters of earthquake faulting.

The amounts and timing of recent and ancient coral reef emergence or submergence events in both volcanic settings and near potentially active faults provides a basis for forecasting the probability of future events (e.g., Sieh et al., 2008). Volcanically related coseismic uplifts may serve as a measure of subsurface volcanic activity such as magma chamber inflation and help scientists to understand the deformation processes affecting volcanic edifices (e.g., Geist et al., 1994; Amelung et al., 2000).

Most reported coseismic vertical reef displacements have occurred in association with thrust-type earthquakes in subduction zones, usually on the main interplate megathrust or decollement. However, the 1992 coseismic uplift of part of the Huon Peninsula reef occurred where the Australian continent has collided with an island arc and probably occurred on a fault developed to accommodate collision deformation rather than being on the interplate megathrust. The 1999 coseismic uplift of the eastern part of Ambrym Island in Vanuatu was related to a  $M_w$  7.5 event on a steeply dipping backthrust reverse fault accommodating eastward displacement of several segments of the central Vanuatu arc system (Pelletier et al., 2000; Regnier et al., 2003).

Crustal displacement associated with seismic fault rupture represents the release of elastic energy stored in the lithosphere that accumulated during the interseismic period preceding the earthquake. Rupture of most convergent margin faults typically involves both horizontal and vertical coseismic displacements that are greatest overlying and adjacent to the fault, but also extending many tens of kilometers beyond the rupture zone. The amount and geographic distribution of vertical displacement may enable mapping of the rupture zone geometry and an assessment of the nature of interplate slip along the megathrust (e.g., Plafker and Savage, 1970; Taylor et al., 1987; Sieh et al., 1999; Briggs et al., 2006; Chlieh et al., 2007; Sieh et al., 2008). Scientists used corals and shorelines to document the geographic pattern of subsidence and uplift as great as 1.5–2 m following the great  $M_w \sim 9.1$  26 December 2004 Aceh earthquake (Bilham et al., 2005; Meltzner et al., 2006; Subarya et al., 2006; Rajendran et al., 2007). The measurements of uplift and subsidence constrained the temporal and spatial extent of the earthquake rupture geometry and processes (Subarya et al., 2006).

Where elastic strain release on a thrust fault or megathrust culminates in coseismic uplift and subsidence of the forearc, one can assume that the event represents only one stage in the greater long-term earthquake cycle of repeated elastic strain accumulation and coseismic release (e.g., Plafker and Savage, 1970; Savage, 1983; Sieh et al., 2008). Elastic strain typically accumulates for tens or even thousands of years prior to coseismic rupture; while strain accumulates there is slow subsidence over the locked part of a thrust fault zone, opposite to the direction of coseismic uplift (e.g., Savage, 1983). Thus, an area of coseismic coral reef uplift is likely to become an area of interseismic coral reef subsidence. If the system was

purely elastic, then over the entire cycle, the coseismic deformation would remove all of the elastic deformation accumulated during the interseismic period. However, in reality, this seldom is the case because usually there is some long-term permanent tectonic deformation over the course of an earthquake cycle (e.g., Taylor et al., 1987; Briggs et al., 2008).

### Methods to measure coseismic coral reef emergence

Precise systematic measurements of uplift, as well as subsidence, should be conducted soon after reefs are affected by earthquakes. Immediately following coseismic displacement post-seismic visco-elastic adjustments often rapidly modify the original coseismic deformation pattern. If one can measure the geography of coseismic vertical deformation soon after an earthquake, then later measurements may reveal the geographic pattern and rates of post-seismic vertical deformation.

Measurements of coseismic uplift and subsidence typically are based on the heights of corals killed by emergence relative to mean low-water (tide) level, or some other datum related to their normal shallowest depth. Taylor et al. (1987) called the shallowest level that a coral could live and grow as its “highest level of survival (HLS),” a term since adopted by other workers (e.g., Zachariasen et al., 1999; Meltzner et al., 2006).

Although other reef organisms such as coralline algae also can be used to measure uplift (e.g., Pelletier et al., 2000), corals are believed to define emergence to within a few cm (e.g., Briggs et al., 2006). Taylor et al. (1980) initiated the practice of measuring the height of numerous emerged corals of a given species relative to nearby still-living corals of the same species, thus obviating the need to establish a tidal datum for each measurement locality. The HLS for head coral genera such as *Porites* and *Goniastrea* have different relationships to sea level so that comparing the height of one genus or species to another would be likely to introduce errors. An inexpensive auto level, tripod, and rod enable quite precise measurements between numerous living and emerged corals.

In a few cases, GPS survey marks have been emplaced prior to coseismic reef displacement and then re-measured after an event (e.g., Subarya et al., 2006). The precision for GPS measurements of vertical displacement is on the order of 2 cm. A limitation of GPS is that few points have been measured and even when many more exist, coral methods probably will remain important for areas where there are no GPS measurements.

Meltzner et al. (2006) used satellite observations to estimate vertical reef displacements by observing the pinkish to red false color on ASTER, QuickBird, and other satellite images of the December 2004 Sumatra-Andamans event. These colors indicate emerged coral overgrown by algae, which occurs within days after a coral dies from emergence. They compared pre- and post-seismic images and used a tide model to estimate the tide levels at the time when each

photograph was taken. Several studies have used before and after Synthetic Aperture Radar (SAR) satellite images to estimate the amounts of coseismic vertical displacement (e.g., Tobita et al., 2006; Lubis and Isezaki, 2008).

Fieldwork in the Mentawai Islands off Sumatra has led to refinement of techniques and the term “coral geodesy” or “paleo-geodesy” to describe the use of corals to document past vertical tectonic motions (Zachariasen et al., 1999, 2000; Sieh et al., 1999; Briggs et al., 2006; Meltzner et al., 2006; Natawidjaja et al., 2006, 2007; Sieh et al., 2008). Micro atolls can record the details of coseismic and interseismic vertical motions over many decades. Annual density bands within coral heads can reveal the timing of relative sea-level changes and the absolute age can be determined using Uranium-series dates (Figure 4).

### Recognition of coseismically emerged reefs

Scientists are unlikely to actually witness coseismic vertical displacement and thus the coseismic relationship to displacements generally depends on the testimony of witnesses. However, local observers may not notice small vertical movements or they may have occurred in the past when there was no oral or written record of the uplift or an earthquake. The presence of well-preserved emerged corals (Figure 3) and teleseismic or historical records of earthquakes can provide strong evidence that vertical deformation was coseismic even if living witnesses did not notice it.

After uplift, erosion and degradation of the coral record commence immediately. This can be particularly severe for corals not uplifted above the intertidal zone where bioerosion is most intense. If uplifted corals remain well preserved for hundreds of years (e.g., Fig. 3), it is

**Earthquakes and Emergence or Submergence of Coral Reefs, Figure 3** Coral head that died ~1729 A. D. is now 2.3 m ALC. This coral is 1.1 m higher than coral that was subsequently uplifted about 1.2 m on 11 August 1965. Good preservation of the coral surface indicates that it initially emerged well above high tide level and can thus be inferred to be coseismically uplifted.

**Earthquakes and Emergence or Submergence of Coral Reefs, Figure 4** (a) X-radiograph of a coral head from the south coast of Guadalcanal, Solomon Islands, showing its annual bands. This coral records a series of relative sea level changes that may or may not be tectonic except for a final uplift of more than 1 m during a sequence of large earthquakes in 1977 that completely emerged and killed the coral. The labels with numbers and years track the sequence of relative sea-level changes that affected the coral. (b) Graph showing the relative sea-level changes that the coral head underwent with time control from the coral's annual banding.

sometimes possible to infer that a prehistoric earthquake caused uplift. On Malakula Island, Vanuatu, we find corals that were uplifted about 1.2 m in 1965. A  $\sim 1.2$  m higher than the 1965 corals are older corals that were uplifted during a previous event in about A.D.1729 (Taylor et al., 1990). The preservation of these higher-level corals is evidence that the uplift that killed them was about  $\sim 1$  m. Had the initial uplift been only  $\sim 0.5$  m, then the corals would have been submerged during high tides and would have been exposed to severe bioerosion.

### Determining the ages of vertical displacements recorded by corals

Several dating methods may be used to constrain the timing of coral emergence. If partially emerged coral heads are still living, annual density growth bands may be revealed by X-radiographs of a slab and the timing of emergence events can be determined by counting annual density bands inward from the living surface (e.g., Taylor et al., 1987; Buddemeier and Taylor, 1998) (Figure 4). If a coral is completely dead then it may be dated by

radiocarbon or by  $^{230}\text{Th}/^{234}\text{U}$ , a method precise to about 1% of the age (e.g., Edwards et al., 1989; Shen et al., 2008). Combining  $^{230}\text{Th}$  and density band counting can date multiple relative sea-level changes recorded within a dead coral head that is hundreds or even thousands of years old (e.g., Zachariasen et al., 1999).

## Summary/outlook

Methods to document and measure coral reef emergence and submergence are now well developed and comprise an important contribution to the understanding of earthquake rupture and the subduction process. Coral micro atolls record the details of both uplift and subsidence over recent centuries or even millennia. Space-based GPS and radar methods have greatly improved the temporal resolution of measurements and can measure horizontal strain as well as vertical motions. With numerous scientists aware of the scientific value of coseismically emerged and submerged coral reefs, it is likely that most future large events will be measured adequately. Smaller ones are not likely to be recognized and investigated unless they occur in an area that is easily accessible or are located in an area of particular scientific interest where GPS survey marks already exist.

## EAST INDIES TRIANGLE OF BIODIVERSITY

Carden C. Wallace  
 Museum of Tropical Queensland, Townsville, Australia

## Synonyms

Centre of diversity; Coral triangle; Indo-Australian Arc; Indo-Malayan centre of maximum diversity; Oost-Indischen Archipel (Dutch); The Malay Archipelago

## Definition

The East Indies Triangle of biodiversity (EITB) refers to the region between the Indian and Pacific Oceans, including Indonesia, the Philippines, Papua New Guinea, Solomon Islands, Timor Leste, part of Malaysia, and some adjacent land and sea. The boundaries of the region have been variously drawn over time, based on estimations of where the greatest marine biodiversity is found (Figures 1 and 3).

## Introduction

Many animal and plant groups show their greatest species richness in the EITB, resulting in a general biodiversity not matched elsewhere in the world. This richness is evident in coral reefs and associated habitats as well as the deep seas that surround them (Paulay, 1997; Allen, 2002; Hoeksema, 2007; Cairns, 2007; Renema et al., 2008). Although species are still being discovered, and precise numbers not available for any group, it is now clear that the greatest number of reef-building coral genera and species occur in this region (Hoeksema, 2007 and contained references), as well as reef-associated fish, mollusks and crustaceans (e.g., Findley and Finley, 2001; Allen, 2002; Meyer, 2003; Table 2 of Hoeksema, 2007). Less documented in compilations but evidenced in numerous taxonomic and other sources is a great richness of small commensal, cryptic, parasitic, and symbiotic organisms from these and other groups such as Echinodermata, associated with coral reef organisms. There is strong scientific interest in identifying the source of this high biodiversity.

Although mainly interested in terrestrial organisms, the great evolutionary biologist and biogeographer Alfred Russell Wallace was aware of the significance of the marine fauna of the Malay Archipelago, commenting after a drift in a boat across Ambon Harbor that “There is perhaps no spot in the world richer in marine productions,

corals, shells and fishes, than the harbor of Amboyna” (Wallace, 1869). A triangle (Figure 1) was used to enclose the general area of the marine East Indies by Briggs (1987), who later provided persuasive evidence to demonstrate that this was also a “center of origin,” from which marine animals dispersed in all directions (Briggs, 1992). Another strong influence on the “center of origin” hypothesis came from a study of the distribution of coral genera throughout the Indo-Pacific (Stehli and Wells, 1971). This idea had much acceptance and has strongly influenced thinking about the marine biogeography of the Indo-Pacific: however, it begged the question of how so much origination occurred, and it was not formally testable. The biogeography of land animals and plants within the same region has been extensively tested against a growing body of knowledge about the tectonic history of the Southeast (SE) Asian region, and timing of events relevant to large-scale isolation and subsequent evolution of fauna and flora (Audley-Charles, 1987; Whitmore, 1981, 1987; Michaux, 1991; Metcalf, 2001). These findings indicate that the complexity of geological and hydrodynamic events and variety of their timing have contributed to a layering of evolutionary and biogeographic patterns in this region.

This kind of information has been more difficult to assess for the marine biota. The sea, which isolates land masses, connects marine habitats. It carries the larvae and/or adults of marine animals, while land masses form the main isolating barriers to sea regions (Pandolfi, 1992). Eustatic events (sea-level changes) cause marine connections to close and reopen from low to high sea stands. Progress in assessing the evolutionary and biogeographic consequences of this history of changing land and sea distribution, sea levels, and connectivity has been made using a number of approaches (e.g., Pandolfi, 1992; Barber et al., 2000; Bellwood and Wainright, 2002; Kirkendale and Meyer, 2002; Wallace, 2001, 2002; Wallace et al., 2002; Hoeksema, 2007, and contained references).

**East Indies Triangle of Biodiversity, Figure 1** The area of the central Indo-Pacific designated as the “East Indies centre of evolutionary radiation” by Biggs (1987).

## Tectonic and oceanographic basis

Coral reefs, and indeed even locations suitable for the development of reefs, were lacking in the central Indo-Pacific during the Paleogene period (65–23 million years ago), whereas extensive development of coral reefs was taking place in a warm, shallow Mediterranean region (Wilson and Rosen, 1998; Perrin, 2002). At this time, a 3,000-km-wide oceanic void, with few shallow water areas or landmasses, existed between Australia and the Southeast Asian mainland (Wilson and Rosen, 1998). This gap gradually narrowed as the Australasian craton moved northward, and shallow water areas emerged, which were eminently suitable for the development of coral reefs (Wallace and Rosen, 2006). The carbonate record in SE Asia indicates that marine and atmospheric conditions for enhanced coral growth and therefore reef formation gradually improved during this process, leading to an “order of magnitude expansion of shallow carbonate

**East Indies Triangle of Biodiversity, Figure 2** Influences proposed to have contributed to the world-greatest biodiversity and distribution of staghorn corals (genus *Acropora*) in the Indo-Australian arc by Wallace (2001, 2002). (a) Separation of the Pacific and Indian oceans, at its most effective during the Late Miocene: deep ocean basins also developed around this time and are proposed to have influenced the evolution of endemic species (Based on Miocene land and sea forms from Hall, 1998). (b) Invasion of the eastern Indian Ocean by Pacific species is now promoted through the influence of the Indonesian through-flow current.

areas” in the Early Miocene (Wilson, 2008). The collision of the Asian and Australian plates produced today’s island archipelagos of SE Asia – the EITB – a composite of fragments which came from various locations throughout the now Indo-Pacific (Michaux, 1991; Hall and Blundell, 1996; Hall and Holloway, 1998). Volcanism and localized dynamic change due to earthquakes and tsunamis still impact on coral reefs in the region (see Wilkinson et al., 2006 and entry *Tsunami*).

The EITB archipelago consists of two broad types of islands and reefs. Some sit on the continental shelf of the Asian and Australian continental plates, and their surrounding seas are shallow (<200 m). Others rise from the deep waters between the shelves (depths to 3,000 m). The greatest diversity of corals and fishes is in the latter non-continental area (“Wallacea”), where the deep seas have allowed reefs to persist continuously for thousands to millions of years, through sea-level changes in excess

**East Indies Triangle of Biodiversity, Figure 3** Boundaries of the region covered by the Coral Triangle Initiative (*dotted line*), encompassing six countries as indicated.

of 100 m that periodically left the shelf reefs and their own shallow portions high and dry. Another key feature of the region is its oceanography (see entry *Indonesian Reefs*). The most significant feature of which is the Indonesian through-flow, a seasonably varying flow of water which travels southwestward from the Pacific Ocean through central Indonesia into the Indian Ocean (Gordon and Fine, 1996; Shriver and Hurlburt, 1997). A third feature of the area is the great variety of habitat types it affords for populations of coral reef species and reef development, from shallow sheltered bays to deep swell-exposed outer slopes (see entry *Corals: Environmental Controls on Growth*). This range of environments and habitats is a critical contemporary determinant of the EITB's diversity, distribution, and abundance of reef species, as outlined, for example, in a distribution study of mushroom corals (family Fungiidae) by Hoeksema (2007).

The EITB's richness of coral species (Veron, 1995; Paulay, 1997; Hoeksema, 2007) is also exemplified by staghorn *Acropora* corals, whose greatest diversity of species per area occurs there (Wallace and Wolstenholme, 1998; Wallace et al., 2001). These authors postulate three major evolutionary and biogeographic influences on the current species richness and distribution patterns of *Acropora*, which are also likely applicable to the majority of coral reef genera (Figure 2). Present *Acropora* species patterns appear to reflect speciation in the Indian and Pacific Oceans due to genetic isolation of subpopulations caused by Mid Miocene tectonic events, leading to a barrier between the oceans (Figure 2a). At the same time, deep ocean basins were formed (Hall, 1998), which are proposed to have influenced the origination and retention

of endemic species (Figure 2a). Last, in more recent time, the Indonesian through-flow current (Gordon and Fine, 1996) would have allowed larval dispersal of Pacific species into the Indo-Australian Arc and through to the eastern edge of the Indian Ocean, while central and western Indian Ocean species remain isolated because of the absence of a return flow (Figure 2b).

### Coral triangle conservation initiative

Concerns have been raised for the future of the EITB, based on the recognition of the general effects on coral reefs of decades of destructive fishing, overfishing, and pollution (Wilkinson, 1998), compounded by severe bleaching events in the Indian and Pacific oceans (1998 and 2002) and the 2004 Asian tsunami (Wilkinson et al., 2006) and other major changes in sea-surface temperature and ocean chemistry due to global climate change (Lough, 2000; Kleypas et al., 2001). To indicate more accurately the extent of the highest biodiversity region, the boundaries of the "triangle" were changed (Figure 3). In 2009 an inter-governmental policy agreement, the "Coral Triangle Initiative" (CTI), was signed by the governments of Indonesia, Malaysia, Papua New Guinea, the Philippines, the Solomon Islands, and Timor-Leste, all countries with territory in the new "triangle" (Anonymous, 2009).

The goals of CTI are: (1) as a priority, to designate and effectively manage "priority seascapes" encompassing the major high-diversity coastal regions; (2) to establish an ecosystem approach to fisheries management; (3) to establish and effectively manage a system of marine protected areas; (4) to establish a regionwide early action plan for

climate change adaptation and (5) to improve the conservation status of sharks, sea turtles, seabirds, marine mammals, corals, seagrass, mangroves, and other identified threatened species (Anonymous, 2009). Government sponsorship of the CTI is supplemented by commitments from major non-government organizations such as WWF, the Nature Conservancy and Conservation International, as well as governments of neighboring and other countries.

## Summary

Biodiversity and endemism of the world's living coral reefs are greatest within the waters and islands between the Asian and Australian continental shelves. The origins of this situation relate to the complex tectonic history of the region, and the hydrological systems associated with it, both now and in the past, as well as to the great extent and variety of coral reef habitats present. This knowledge, along with insights from molecular genetics and improved data about the biodiversity, paleontology, and phylogeography of many animal and plant groups, is contributing to a better documentation of marine faunal and floral patterns of the region. However, much remains to be understood, and many new species await description. An initiative to provide broad conservation management for coral reefs within the territories of six countries aims to provide protection for all species in the region by a series of measures.

## EASTERN CARIBBEAN CORAL REEFS

---

Dennis Hubbard  
 Oberlin College, Oberlin, OH, USA

## Synonyms

Holocene reefs of the SE Caribbean; Modern SE Caribbean reefs; SE Caribbean reefs

## Definition

Eastern Caribbean Coral Reefs are biologically mediated structures that have formed since the last lowstand of sea level and are associated with islands and platforms to the east and south of the Island of Hispaniola in the Caribbean Sea.

## Reef types

The present-day Caribbean Sea was formed between 200 and 130 million years ago as the Caribbean Plate moved eastward, forcing North and South America apart (Pindell et al., 1988). The eastern Caribbean is defined on the north by faults and islands, on the south by South America, and to the east by the Antilles Arc and the Atlantic Ocean (Figure 1). With a few notable exceptions, most islands in the Antilles chain have igneous origins and steep slopes that leave little opportunity for extensive barrier reef formation.

For the purpose of this chapter, Caribbean reefs are divided into three categories: fringing, barrier, and shelf-edge reefs. This provides a simple frame of reference for the discussion below, and is not proposed as an alternative to any of the classification schemes that already exist.

*Fringing reefs* form along steep insular margins (Figure 2). As a result, reefs are close to shore, and lagoons are small and shallow (<100 m wide and <2 m deep). Individual reefs rarely exceed a few hundred meters in length. Where the foreshore slope is gentle or flat, *barrier reefs* form 0.5–3 km from shore in front of well-developed lagoons (Figure 3). They extend for 1–2 km alongshore and effectively protect the bay from open-Caribbean processes. Their location is often tied to antecedent topographic benches, but they are also formed atop loose rubble shoals dominated by bioclastic debris (Adey and Burke, 1976) that may reflect an earlier phase of reef development in which calcification and bioerosion were in balance. Along the margins of many islands and shallow carbonate banks, *shelf-edge reefs* form still-submerged structures that range from thin veneers that mimic antecedent topography to elevated rims that owe their present shape to significant Holocene accretion (Figure 4a). These features can sit seaward of shallower reefs (e.g., Puerto Rico, Hubbard et al., 1997) or stand alone, especially along the edges of submerged platforms (e.g., Saba Bank, Macintyre, 1972). Regularly spaced sand channels that are oriented downslope serve as short-term repositories for excess sediment and as conduits for the offshore transport of sand, especially during storms (Hubbard, 1992). Where they front steep islands (e.g., Cane Bay on St. Croix), the greatest coral abundance often occurs near the shelf edge where the adverse effects of terrestrial runoff are reduced (Figure 4b; Hubbard et al., 1990).

## Oceanography and reef-community structure

Caribbean reef-crest communities tend to vary from massive algal ridges in the eastern Windward Islands, to *Acropora*-dominated reef crests in the Leeward Islands to mostly hardgrounds with scattered, massive corals and fewer branching species to the far west (Adey and Burke, 1977; Geister, 1977). Adey and Burke (1977) demonstrated that wave energy and water quality were important controls over what the reef-crest community looks like and at what depths zonation boundaries occur. As

**Eastern Caribbean Coral Reefs, Figure 1** Location map showing the major physiographic features in the eastern Caribbean. The Caribbean plate is bordered on the north by a series of left-lateral faults and the Greater/Lesser Antilles. The southern boundary sits near South America. Most of the Windward and Leeward Islands are part of an island arc formed as the westward-moving Atlantic Plate slipped beneath the eastward-moving Caribbean. "PR" and "B" mark Puerto Rico and Barbados, respectively. Faults after Pindell et al. (1988).

**Eastern Caribbean Coral Reefs, Figure 2** Air photographs of fringing reefs along the south coast of St. Croix (a) and the eastern side of Nevis (b). In both areas, the nearshore slope drops quickly to the insular shelf and forces the reefs against the coast. Photos by permission of the author.

**Eastern Caribbean Coral Reefs, Figure 3** Air photograph of the barrier reef fronting Christiansted Harbor on the north side of St. Croix. The lagoon is ca. 1 km across. These reefs are significantly further offshore than fringing reefs and provide a clear line of demarcation between offshore and lagoonal processes. Photo by permission of the author.

a proxy, they proposed a “wind index” to reflect the gradual loss in wind and wave energy moving northward toward the “horse latitudes.” This is clearly reflected in the rose diagrams in Figure 5 based on synoptic, fair-weather wave data compiled by the US Navy. Hubbard (1989) proposed that hurricane frequency and intensity might also play a role in this equation. Using detailed records for the previous century, the likelihood of major storms passing through 1-degree grid squares across the Caribbean and western Atlantic were tabulated. Contours of the highest return frequencies were used to identify the most likely storm tracks through the region (red arrows in Figure 5).

The highest fair-weather waves plus the most common and severe storms occur near the boundary between the Windward and Leeward Islands. Near Guadalupe, Category 3–5 hurricanes strike almost annually, minimizing branching acroporids along the reef crest. In the interim, Atlantic swell creates a high-energy environment that discourages grazing. The result is an accumulation of coralline algae that build thick, wave-resistant structures (Adey and Burke, 1976, 1977: see area 1 in Figure 5). In the northwestern Caribbean and western Atlantic (area 2 in Figure 5), storms are still common but generally less severe. Fair-weather wave climate is benign compared to the more exposed Windward Islands. Because *Acropora palmata* is extremely sensitive to sediment stress (Adey et al., 1977b; Rogers, 1983), it relies on wave action to clear sediment. Thus, a reef-crest community dominated by branching corals is difficult to support in all but the most energetic areas (e.g., where winter swell impacts the Bahamas). Smaller waves also make grazing easier, precluding the accumulation of thick coralline crusts (Adey and Burke, 1977). Reef crests dominated by hardgrounds and massive corals tend to be

**Eastern Caribbean Coral Reefs, Figure 4** (a) Stylized drawing of a Caribbean shelf-edge reef. In this example, the antecedent Pleistocene topography has been accentuated by Holocene accretion. Channels through the reef facilitate sediment storage and removal. (b) Graph summarizing the abundance of corals (black line) and carbonate production (red) across the narrow insular shelf at Cane Bay on St. Croix. Note that the greatest coral cover and carbonate production occur near the shelf edge where sedimentation is low. After Hubbard et al. (2008) with permission by Springer.

**Eastern Caribbean Coral Reefs, Figure 5** Caribbean reef type versus fair-weather wave climate and storm frequency. The “petals” on the “rose diagrams” (in red) are proportional to the total wave energy from a particular direction, based on wind and wave data from the US Navy Synoptic Survey of Meteorological Observations (SSMO). The solid (hurricanes) and dashed (tropical storms) arrows characterize the primary storm paths through the region. Major storms cross directly through the easternmost Caribbean (area 1) on an annual basis. High storm frequency and vigorous day-to-day waves discourage acroporids and intense grazing. The result is an accumulation of thick and wave-resistant ridges built by coralline algae (Adey and Burke, 1977). *Acropora palmata* is often found but in deeper water where wave action is buffered. The more modest wave climate and the greater proximity to sources of terrestrial sedimentation in the northwestern Caribbean (area 2) favor massive corals over branching *A. palmata*, which depends on wave action to clear sediment. In the northern Leeward Islands and the Lesser Antilles (area 3), intermediate fair-weather wave climate and moderate storm intensity/frequency provide an ideal environment for branching and smaller encrusting forms in shallow water. From Hubbard et al. (2008) with permission of Springer.

the norm. The intermediate wave climate of the northeastern Caribbean (area 3 in Figure 5) provides the ideal environment for a well-zoned reef front that ranges from encrusting and branching forms near the surface to massive and platy corals at greater depths. Because these islands exist in a transitional area, relatively small changes in shoreline orientation can result in any of the three reef-crest communities just described, depending on exposure and storm proximity. For example, well-developed *A. palmata* reefs flourished along the northeastern coast of St. Croix until the arrival of White Band Disease in the late 1970s. In contrast, the south side of the island is more exposed to southeasterly Caribbean swell and storms passing to the south (Figure 5). This encourages algal ridges that are similar to but less extensive than those found in the northern Windward Islands (Adey, 1975). Along the less exposed northwestern shelf, massive corals dominate

the sloping shoreface, and *A. palmata* has been a minor contributor to reef accretion over at least the past 3,500 years (Hubbard et al., 1986).

### Holocene reef geology in the southeastern Caribbean

Throughout the late 1970s, the Smithsonian Institution mounted an aggressive investigation of late Holocene reefs throughout the Caribbean. The articles from these studies still provide the most comprehensive treatment of shallow reefs in the region (Adey, 1975; Adey et al., 1977a,b; Adey and Burke, 1976, 1977). Since these early studies, core investigations have expanded to include other shallow reefs on St. Croix (Hubbard et al., 1986, 2005; Burke et al., 1989), Antigua (Macintyre et al., 1985), and Vieques (Macintyre et al., 1983) plus deeper shelf-edge features

(Adey et al., 1977b; Hubbard et al., 1986, 1997, 2005, 2008; Macintyre et al., 1981) and abandoned Holocene reefs that formed during the most rapid part of the Holocene sea-level rise (Fairbanks, 1989; Bard et al., 1990).

### Deep Holocene reefs

Along the steep slopes beneath many Caribbean shelf margins, submerged ridges and terraces were flooded by rapidly rising sea level (Jukes-Browne and Harrison, 1891; Vaughn, 1916; Davis, 1926; Macintyre, 1972). Cores by Fairbanks (1989) have documented an early Holocene origin for three submerged reefs off Barbados (Figure 6b: RFG-7, 9, 12), and similar scenarios are probable throughout the region (e.g., see Sherman et al., 2010 for a discussion of deep mesophotic reefs off southwestern Puerto Rico). The ephemeral nature and sudden back-stepping of the deep reefs off Barbados were explained as responses to two decameter-scale jumps in sea level starting ca. 14,000 and 11,400 years ago. This was supported by isotopic data that suggested a rapid release of meltwater at these times (Fairbanks, 1989). Stanford et al. (2006) have proposed that the older 16 m rise in sea level could have occurred in as little as 200 years. Most recently, Bard et al. (2010) have called the second jump into question based on new core data from Tahiti.

Regardless of their absolute history, these cores demonstrate that well-developed Holocene reefs built structures

10–20 m thick along the steep margin of Barbados under a regime of rapidly rising sea level (avg.  $\sim 5\text{--}7$  m/ky). Each reef was eventually abandoned and a new one formed upslope (back-stepping). It should be noted that the top of each abandoned reef and the base of its upslope neighbor coexisted at similar depths (see Fig. 1 in Fairbanks, 1989). Furthermore, *A. palmata* remained dominant near the top of each abandoned reef as a similar community was developing along the new, upslope feature. It has been suggested that Pleistocene lowstands have necessitated a period of highstand “reassembly” in which the zonation pattern was reestablished (Jackson, 1992; Pandolfi, 1996). Inherent in this concept is a significant disruption of community structure associated with low-stands of sea level. However, the potential for community disruption even during the fastest sea-level change is small on the temporal scale in which larval dispersal and recruitment occur. The Barbados cores demonstrate a clear connection between successive reefs that allowed community structure to be transmitted upslope even when individual reefs could not.

### Shelf-edge reefs

The next major episode of reef building began with platform flooding throughout the region. Three cores along the southern margin of Lang Bank, east of St. Croix, provided our first glimpse of these features and became the

**Eastern Caribbean Coral Reefs, Figure 6** (a) Scenario of reef development on southwest Lang Bank east of St. Croix as described by Adey et al. (1977b). Earliest shelf-edge *Acropora palmata* reefs (red circle in (b)) were killed ca. 10,000 years ago by sediment-laden water shed from Lang Bank during flooding, a condition that persisted until 8,000–7,000 years ago (“Dirty Water” in (b)). By the time these “inimical bank waters” cleared, water depth was too deep for fast-growing *A. palmata*, and the new reefs were dominated by massive species (green squares in (b)), which led to slower but continuous accretion until today. (b) Calibrated radiocarbon ages from Adey et al. (1977b). Because of similar platforms elsewhere in the region, it was presumed that this pattern would generally persist for similar sites as new core data became available. (c) Summary of available radiocarbon data for Caribbean shelf-edge reefs. Other reefs on Lang Bank (E STX: Hubbard et al., 2005), Puerto Rico (PR: Hubbard et al., 1997; Hubbard, unpublished data), and elsewhere in the western Caribbean/Atlantic (Other: Lighty et al., 1982; Macintyre et al., 1985; Toscano, 1996; Toscano and Lundberg, 1998) flourished throughout the period of “dirty” water proposed for Lang Bank and extrapolated to other Caribbean sites in existing models (shaded gray). These reefs were dominated by branching *A. palmata* closest to the shelf edge and massive species in the backreef at sites where multiple cores were taken. After “Coral Reefs: Biology, Geology & Politics: an e text” with the author’s permission.

foundation of a broader Caribbean model for Holocene reef development. According to Adey et al. (1977b), early *A. palmata* reefs formed near the shelf break by at least 10,500 cal BP, but were soon killed by turbid water derived from the reworking of long-exposed terrestrial silts and clays atop the platform and landward of their core site (Figure 6a; “inimical bank waters” of Schlager, 1981). Nutrients adsorbed to fine-grained sediments (especially siliciclastic clays) could also have discouraged calcification (phosphorous) and encouraged algae (nitrogen), as well as bioerosion, which is also favored by increased nutrients (Moore and Shedd, 1977; Edinger and Risk, 1997). Based on the Lang Bank cores, Adey (1978) concluded that, “from about [10,200] to [5,800] years ago, apparently very little reef development occurred on the island of St. Croix.” (Bracketed values are corrected from the raw  $^{14}\text{C}$  measurements.) Reef accretion may have started again on Lang Bank as early as 7,800–7,000 years ago (adjusted from the raw  $^{14}\text{C}$  ages in their Fig. 4 of Adey et al., 1977b).

More recent shelf-edge cores from St. Croix (Hubbard et al., 2004, 2005, 2008) confirm that the inhibition of reef development around the island was not as dramatic as has been assumed. This pattern is repeated in cores from similar systems off southwestern Puerto Rico (Hubbard et al., 1997) and Florida (Lighty et al., 1978; Toscano and Lundberg, 1998), where “inimical bank waters” played a role that was more variable and of shorter duration than previously described (Figures 6c and 7). Cores from the northern margin of Lang Bank show a delay in reef accretion until ca. 8,000 years ago (Hubbard et al., 2005, 2008, unpublished data). However, these reefs were dominated by *A. palmata* and not massive species as had been assumed. Along the southern margin, less than 5 km east of the Smithsonian core site, accretion had started by at least 9,300 years ago. Based on the corrected curve of Lighty et al. (1982) (see Hubbard et al., 2000, 2002, 2005; Toscano and Macintyre, 2003 for details), the antecedent Pleistocene surface would have flooded less than 1,000 years prior (Figure 7). As was the case to the north, branching corals dominated the reef crest and continued to do so until after 6,500 cal BP (Hubbard et al., 2004; Hubbard, 2009b). Along the eastern tip of Lang Bank, the oldest date from a core through the reef crest was 8,000 cal BP, but nearly 5 m of undated section separates it from the underlying Pleistocene surface at a depth of over 30 m below present sea level. Based on the accretion rate for the upper 12 m of core, this reef could have started as early as 9,500 years ago, with a longer lag period (~2,000 years), despite its position on the most upwind margin Lang Bank. Thus, *A. palmata* reefs were present along the upper shelf rim as early as 9,500 years ago, and, once accretion began at any site, reef building and community structure remained constant for at least 1,000 years beyond the proposed IBW-hiatus (Figures 6c and 7; Hubbard et al., 2008).

Along the southwestern corner of Puerto Rico, samples 1–2 m above the base of the Holocene section at two shelf-

**Eastern Caribbean Coral Reefs, Figure 7** More detailed summary of selected Caribbean shelf-edge cores. The colored bands correspond to the intervals of reef start-up (red), abandonment due to “inimical bank waters” (gray) and recolonization by slower-growing massive corals (green) proposed by existing Caribbean models. Circles denote *Acropora palmata*; squares are massive species. Dark blue bars show depths of antecedent substrates below present sea level. Light blue shaded intervals indicate nonaccretion following bank flooding at each site. Reef accretion between 10,000 and 8,000 years ago was clearly more important than has been assumed. Also, accretion by rapidly growing acroporids continued afterward at many sites.

edge sites yielded radiocarbon ages of 9,300 and 9,500 cal BP (Hubbard et al., 1997), consistent with the oldest ages from the shallow rim of Lang Bank sitting at similar depths. As on St. Croix, both sites were dominated by *A. palmata* from the time when they first started to build until ca. 7,000 years ago (i.e., they flourished across the proposed hiatus and beyond). Based on the average accretion rate for the two cores (4.3 m/ky) and the documented antecedent depth of –27 m, little or no lag existed between shelf flooding and the initiation of reef preservation (Figure 7).

Figure 6c summarizes available data for ages and depths of shelf-edge reef samples throughout the Caribbean. Figure 7 provides more detail for individual shelf-edge cores from Lang Bank, Puerto Rico, and Florida. The density of data is lower prior to 8,000 years ago, owing to fewer cores having been recovered from these more logistically difficult environments. Nevertheless, it is clear that reef accretion did occur within much of the interval between 10,000 and 6,900 cal BP on both St. Croix and elsewhere in the Caribbean (compare Figure 6b and c). Furthermore, once *A. palmata* reefs were established at a particular site, their community structure remained constant until some time after 7,000 cal BP.

### Inner-shelf reefs

As the inner shelves continued to flood and sea level slowed further, the locus of reef development shifted to progressively shallower sites. As was the case for the deep reefs off Barbados, this “back-stepping” often began before the shelf-edge reefs were abandoned. On Lang Bank, reef accretion along the margin continued until ca. 6,500–6,000 cal BP, over a thousand years after now-emergent reefs to the west had already started up closer to the shore (Adey, 1975; Burke et al., 1989; Hubbard et al., 2005; Macintyre et al., 2008). Similarly, when the shelf-edge reefs off southwestern Puerto Rico were abandoned (~6,800 cal BP), the mid-shelf reefs had already been active for nearly a millennium (Hubbard et al., 1997). In many instances, these shallower reefs sat atop antecedent highs, but Adey (1988) showed that some early reefs stabilized mobile bioclastic sand shoals – perhaps equivalent to the detrital intervals described above for many shelf-edge reefs. It is probably not coincidence that presently emergent reefs started to build to sea level at the same time when barrier islands were forming all around the world. While the sources of material were different, slowing of sea level facilitated the filling of accommodation space in both instances.

### What have we learned?

While this section focuses on the southeastern Caribbean, lessons have been learned that are applicable to the broader Caribbean. Cores off Barbados (Fairbanks, 1989) have verified earlier suggestions that reefs below the edges of many platforms are probably relict Holocene features left behind by rapidly rising sea level (Vaughan, 1916; Macintyre, 1972). The potential importance of sudden and rapid upward shifts in sea level has also been clearly demonstrated.

### The role of “inimical bank waters”

The earlier models of Adey (1978) and Macintyre (1988) introduced the idea that turbid water associated with platform flooding retarded reef building for up to 4,000 years along Lang Bank until water quality improved. While poor water quality undoubtedly played an important role in early shelf-edge reef accretion on St. Croix, its effects were more complex and perhaps shorter-lived than has been assumed. Throughout the region, active *A. palmata* reefs built uninterrupted across much of the interval for which reef-building was previously characterized as minimal. Many of these reefs continued to flourish until 7,000 cal BP and beyond.

Bioclastic debris near the base of many cores may reflect an additional mechanism that is more indirectly related to flooding – intense bioerosion driven by elevated nutrient levels (Schlager, 1981; Hallock and Schlager, 1986). Adey and Burke (1976) described significant detrital intervals beneath the shallow “bank-barrier” reefs on northeastern St. Croix and concluded that this represented stabilization by an early coral community followed by active coral-dominated accretion. Similar patterns have

been documented along the shelf margins described above and may represent an early standoff between carbonate production and bioerosion. An important lesson here is that the oldest preserved corals need not reflect the first appearance of coral communities with reef-building potential. Thus, water quality may have been adequate to support widespread coral growth but not reef accretion.

### St. Croix as a “Caribbean model”

Because many shelf and platform margins throughout the Caribbean sit at water depths similar to Lang Bank, the scenario from St. Croix was extended to western Atlantic platforms under the influence of medium to high energy: “Where the shelf edge is between 10 and 30 m, early Holocene reefs were killed off owing to turbidity, and continuous Holocene reef building did not occur adjacent to deep oceanic waters” (Adey, 1988). “By the time water conditions returned to normal, the advancing seas were too deep to allow shallow-water communities of *A. palmata* to reestablish. The rapid reef growth of these communities was thus transferred to shallow-water substrates adjacent to coastlines” (Macintyre, 1988). More recent studies have shown that local tectonic and varying oceanographic processes have resulted in significant variability in antecedent topography, both regionally (see Fig. 3 in Adey, 1978) and locally (Burke et al., 1989; Macintyre et al., 2008; Hubbard et al., 2005, 2008; Bard et al., 2010). It, therefore, seems more realistic to expect nonsynchronous patterns of shelf flooding, wide variations in the importance of “inimical bank waters,” and varying accretionary histories controlled by the details of antecedent topography and local oceanographic conditions (Hubbard et al., 2008; Macintyre et al., 2008).

### The role of sea level

Figure 8 summarizes our present understanding of Caribbean sea-level rise (a) and reef development (b). The lower sea-level curve is based on core data from Fairbanks (1989) while the upper curve is modified from Lighty et al. (1982). While some studies have challenged the details of this curve (e.g., Gischler and Hudson, 2004), all agree that sea level rose rapidly (avg. ~5–7 m/ky, with shorter-lived episodes of faster rise) until ca. 8,000–6,000 years ago, after which it decreased to rates below 2–3 m/ky.

Whether reefs remain submerged or are close to sea level today was determined primarily by the rate of sea-level rise at the time when they started to build. Hubbard (2009a) calculated an average accretion rate for Caribbean reefs between 3 and 4 m/ky using data from all published Caribbean core logs. The mean accretion rate for reefs dominated by *A. palmata* versus massive species varied by less than 0.5 m/ky at any depth (see their Fig. 6). Similarly, the accretion rate for all paleo-depths between –2.5 and –22.5 m was ~3.5 m/ky, and the differences were statistically insignificant ( $R^2 = 0.003$ ). Short-term accretion rates (i.e., between successive dated samples) were

**Eastern Caribbean Coral Reefs, Figure 8 (a)** Summary of Caribbean sea-level history. The earlier curve (blue) is based on Fairbanks (1989) and Bard et al. (1990). Data for the past 11,000 years (red) are corrected from the Lighty et al. (1982). *Acropora palmata* curve using both proprietary and public-domain software (respectively, Beta Analytic, Inc. and <http://intcal.qub.ac.uk/calib/>). For details, the reader is referred to Hubbard et al. (2000, 2004, 2005) and Toscano and Macintyre (2003). Neumann's (1977) mangrove peat curve for Bermuda (likewise corrected) is shown by the dashed line. (b) Stylized eastern Caribbean profile summarizing available information on reefs between present sea level and a depth of  $-120$  m. The lower profile is drawn from chart data in Bard et al. (2010) and core logs from Fairbanks (1989). The shelf-edge reefs are a composite of St. Croix and Puerto Rico. The inner-shelf reefs are based largely on St. Croix (Hubbard et al., 2008). On St. Croix, the lower shelf-edge reef (1) was active by 10,500 cal BP and reflects the hiatus described in Adey et al. (1977b). The upper shelf-edge reef (2) is based on data from all three sides of Lang Bank. TB/BI = Tague Bay Reef; Buck Island Reef; LR = Long Reef (see Macintyre et al., 2008 for locations). Deeper reefs (RGF-9 m 12, 7) built while sea level was rising rapidly and were sequentially left behind. The shelf-edge reefs (Lang Bank/PR) formed during a transition from rapid to slower sea-level rise. The inner reefs (TB/BI and LR) all formed as sea level was slowing dramatically, and it was easier to fill accommodation space. After "Coral Reefs: Biology, Geology & Politics: an e text" with the author's permission.

variable and did exceed 7 m/ky on occasion. However, these were almost always from short-lived intervals within reefs that were building at much slower rates closer to the regional average of 3–4 m/ky. Similar patterns have been described by Gischler (2007) for Belize and Hopley et al. (2007) for the Great Barrier Reef. Holocene reefs in the western Dominican Republic verify an abrupt change from transgression to regression as the rate of sea-level rise dropped below 3–4 m/ky after 7,000 cal BP (Hubbard et al., 2009).

Early reefs, like those off the southern Barbados shelf, were left behind, despite showing at least brief accretion rates that rivaled sea-level rise. The innermost reefs all around the Caribbean formed around 8,000 years ago as sea level was slowing. This has allowed them to either "keep up" or "catch up" in the interim (Adey and Burke, 1976; Neumann and Macintyre, 1985). The eventual shift in the shelf-edge reef community between 7,000 and 6,000 years ago is enigmatic inasmuch as it occurred at a time when sea level had slowed to the point where it should have been much easier to keep up. This was also

long after bank waters had cleared, and the reefs were still in water depths capable of supporting active accretion. Why *A. palmata* reefs quit throughout the Caribbean, (Hubbard et al., 2005) and why they have shown no evidence of catching up for the past 6,000 years is unclear and may bear on recent events involving this important Caribbean reef building species.

The interaction between sea-level rise and local antecedent topography has been the dominant factor controlling the timing of reef development, subsequent reef accretion patterns, and whether particular reefs are at sea level today. Each episode of reef building followed flooding of slope breaks that provided advantages for reef building (e.g., a hard substrate that facilitated coral recruitment, access to open water for easy sediment removal). Initial coral-dominated accretion lagged behind flooding, owing to a combination of reduced water quality (that retarded coral development) and increased bioerosion (that favored sediment deposition over coral-mediated accretion). Community structure varied from site to site, but *A. palmata* appears to have been the most important

reef crest species along many Caribbean shelf margins until at least 7,000 years ago.

The process of reef drowning and back-stepping often began while the soon-to-be-abandoned seaward reefs were still active. Because depths over the two structures appear to have been similar, it is unclear why the seaward reef would have lagged behind its more protected landward counterpart – which was probably closer to sources of sediment stress. Whatever the sea-level scenario, the movement of larvae from one reef to the next was probably no more difficult than it is today. Thus, efficient larval transfer and a stable reef community can be maintained during periods of rapidly changing sea level even when reef accretion cannot.

### A simpler model

The lower section of the profile in Figure 8b is based on Barbados (Fairbanks, 1989), but similar scenarios probably occurred throughout the region. The shallow reefs are based on St. Croix, but generally mimic Puerto Rico and Florida. Along the shelf-edge, the lower reef (labeled “1”) was cored by Adey et al. (1977b) and formed more than 10,500 years ago. Accretion was compromised as the adjacent ridgetop flooded. Along the raised rim of Lang Bank (labeled “2”), accretion was variable in timing but not structure. At most sites, *A. palmata* dominated the bank top and remained as the primary reef builder until at least 7,000 years ago. Back-stepping to the inner-shelf reefs was variable in both timing (antecedent topography, sea-level elevation and rate of change, physical processes) and community structure (water quality, wave energy). Based on the above discussion, the critical points include:

1. Reef start-up, building, and demise are tied more simply to the relationship between sea-level rise and local topography. In this scenario, less regional synchronicity is anticipated, and whether a reef is presently at sea level is mostly a function of the rate of sea-level rise when accretion began.
2. Both the spatial continuity and temporal persistence of reduced water quality after platform flooding are reduced. Bioerosion was perhaps as important as reduced coral productivity in delaying initial reef preservation.
3. The need for “inimical bank waters” or sudden leaps in sea level to induce reef abandonment or back-stepping (Schlager, 1981) is reduced. Both have undoubtedly played important roles, but the shifting of reefs to shallower sites can be a more orderly and less dramatic process than has been traditionally assumed.
4. Larval dispersal was probably no more difficult during episodes of back-stepping than it is today. Thus, the need for dramatic “reassembly” following deglaciation is minimized.
5. The high accretion rates often cited as “typical” for Caribbean reefs are less common than previously characterized and are rarely representative of the pattern seen throughout the reef in which they were found.

Accretion rates closer to 3–4 m/ky (perhaps 3–6 m/ky on the Great Barrier Reef) are consistent with the decrease in the rate of sea-level rise between 8,000 and 6,000 years ago being a “tipping point” that caused a general shift from transgression to regression.

6. *A. palmata* was probably a more persistent reef builder after platform flooding than has been assumed, and it remained as an important shelf-edge reef builder from 10,000 to at least 7,000 years ago.
7. The eventual decline of *A. palmata* across the region starting around 7,000 years ago is enigmatic inasmuch as any potential for “inimical bank waters” had long passed, sea level was slowing down dramatically, and shelf-edge reefs were well above the accepted depth limit for active reef accretion. Corollary to this, it is not clear why many reefs were abandoned inasmuch as they sat at depths similar to new reefs closer to land and the attendant sources of stress.

## EASTERN INDIAN OCEAN – NORTHERN SECTOR

---

Barbara E. Brown  
 University of Newcastle, Newcastle upon Tyne, UK

### Definition

The northern sector of the eastern Indian Ocean includes the Andaman Sea where fringing reefs are abundant and where many corals appear to show some resistance to elevated temperatures and irradiance levels through the possession of thermotolerant symbiotic algae and enhanced physiological defences.

### Background

The northern sector of the eastern Indian Ocean embraces the Bay of Bengal and also the Andaman Sea, the latter supporting extensive coral reefs which are both high in coral cover and coral diversity (Brown, 2007) and comprising approximately 19% of the surface cover of shallow reefs in the Indian Ocean (Spalding et al., 2001), excluding the reefs of western Australia. Within the Andaman Sea fringing reefs are extensive in the Andaman and Nicobar Islands (India), the Mergui Archipelago (Myanmar), west coasts of Thailand and northwest Sumatra (Indonesia) with limited reef development on the Malaysian coast. Although reefs on the Andaman Sea coast of Thailand have been well worked the majority of reefs in the region have never been visited by scientists because of political restrictions.

The reefs of the Andaman Sea which have been studied in detail have considerable scientific interest, particularly in

the context of changing climatic conditions. Sea temperatures in the region are generally high and change little over the year varying from 28°C in January to a maximum of 29.5°C in May. Over the last 50 years sea temperatures have been rising at a rate of at least 0.126°C per decade (Brown et al., 1996). However, there have been only two extensive bleaching events in 1991 and 1995 which have caused any significant coral mortality – more recent events have been localised with corals frequently recovering relatively quickly after the initial bleaching. The most recent mass bleaching event in the Andaman Sea in May 2010 may however prove a greater test of the resilience of these corals. Almost 20% of the 66 genera recorded in western Thailand host symbiotic algae belonging to Clade D which contains some of the most thermo-tolerant algal types known (LaJeunesse et al., 2010) and intertidal corals, which are abundant throughout the region, boast diverse physiological and biochemical defences to both temperature and light stresses (Brown et al., 2002a; Brown, 2007). The dynamic oceanography of the Andaman Sea and the resulting in-built stress resistance of many of the shallow water corals offer potential for the area to be an important ‘refuge’ during a period of climate change.

### Geological history and sea floor topography

The Andaman Sea has a complex geological history and sea floor topography with major rivers draining into the Bay of Bengal to the north via the Ganges/Brahmaputra delta and also directly into the Andaman basin through the Irrawaddy delta. The latter river makes a significant sedimentary contribution to the Andaman Sea with an annual suspended load of  $300,000 \times 10^3 \text{ mt}$  and an average discharge at its mouth of  $13.6 \times 10^3 \text{ m}^3 \text{ s}^{-1}$ . While sedimentation restricts reef growth in close proximity to these discharges, reefs flourish in inshore turbid settings on all islands and mainland areas bordering the Andaman Sea as well in clearer waters around more offshore islands.

The geological history of the region shapes the topography of the Andaman Sea floor and both the geology and the plate tectonics are extremely complex (Curry, 2005). Here the Indian and Eurasian plates collide and other tectonic features include coupling and decoupling of platelets, crustal movement along fault lines, rotation of continental blocks and the opening of marginal basins, as in the Andaman Sea. There has been much physical upheaval over the last 50 million years in the region with large earthquakes being recorded in the Nicobar islands in 1847, 1881, 1941 and 2004 and 2005 (Bilham et al., 2005). The 2004 earthquake was responsible for the devastating Asian tsunami which caused tragic loss of life across the Indian Ocean together with subsidence of land and reefs in the Nicobars and on the west coast of the Aceh province and uplift of land and reefs on the west coast of Sumatra, and in the Andamans (Meltzner et al., 2006).

The sea floor of the Andaman Sea is dominated by the Malay continental margin with an outer shelf break that occurs with increasing depth southward to a maximum at

7°N latitude with pinnacles of 200 m relief marking the shelf break. The slope descends to a deep terrace, 2435 m deep, before dropping to a trough at 3075 m in the central Andaman Sea. Bounding the western portion of the Andaman Sea is the Andaman-Nicobar Ridge. Major channels cross the ridge and divide the Andaman and Nicobar islands into four groups; the islands are fringed by coral shelves 10–50 km wide west of the islands and 10 km wide on the east. The complex topography of the sea bed around the islands is responsible, at least in part, for the exceptionally dynamic oceanography of the area.

### Oceanography and major physical features

The oceanography of the Andaman Sea is governed by the seasonal reversal of the Asian monsoon. While current flow reverses once a year at shallow depths it is believed that a greater depths of >200 m flow changes three times a year (Potemra et al., 1991). Another critical factor influencing water movement is the semi-diurnal tide with tidal ranges of 1–2 m in the Andaman and Nicobar islands and macrotidal ranges of ~3 m along the Thai coast and >5 m on the Myanmar coastline. The complex topography of the channels described above together with strong tidal influences give rise to some of the largest internal waves ever described (Osborne and Burch, 1980). The waves traverse the Andaman Sea in packets of 4–10 with amplitudes of at least 60 m. Bands of surface rips accompany the waves and these can be observed on satellite images stretching some 10–100 km across the sea surface. The internal waves are a major influence in the transport of energy within the ocean and are likely to have a critical effect on temperature and salinity regimes as does upwelling along the continental shelf (Yesaki and Jantarapagdee, 1981).

Sea levels in the region show both high annual variability and significant anomalies in some years (Dunne and Brown, 2001). Large negative sea level anomalies (>20 cm) are obvious in the long-term record and are a characteristic of the Andaman Sea and eastern Indian Ocean. They are generated as a result of ocean-atmosphere-land interactions that result in a phenomenon known as the Indian Ocean Dipole (Webster et al., 1999). This produces a warming in the western basin of the Indian Ocean with higher sea levels and reduced upwelling while in the eastern Indian Ocean sea levels are depressed and upwelling enhanced. Indian Ocean Dipole events were noted recently in 1997–1998, 2003 and 2006–2007 (Brown, 2007; Behera et al., 2008; Rao et al., 2009). Despite these negative sea level anomalies sea level has been steadily rising on the west coast of Thailand at a rate of 28mm per decade over the last 40 years (Tanzil et al., 2009), a fact confirmed by Church et al. (2004) who showed that sea level was rising faster in the north-eastern Indian Ocean, over the last 50 years, than anywhere else in the world. A possible factor inducing this effect may be the recent trend of declining winter and spring snow cover over Eurasia which causes a land ocean thermal gradient that favours stronger south west monsoon winds across the Indian Ocean (Goes et al., 2005).

### Biology of coral reefs of the Andaman Sea

The geology and oceanography of the Andaman Sea have strongly influenced not only the distribution and morphology of reefs in the region but also their resistance and resilience to environmental perturbations. Extensive intertidal reef flats are found throughout the region with sheltered sites being dominated by *Porites* and faviid species while more wave exposed locations are dominated by branching *Acropora* spp., *Pocillopora damicornis* and *Montipora digitata*. Subtidal reefs on the mainland coast of Thailand are found growing to depths of 5–15 m whereas those on offshore islands are found in depths down to 30 m. The most abundant species in deeper water are *Porites lutea*, *Acropora intermedia*, *A. muricata* and *Porites rus* (Phongsuwan and Chansang, 1992). Similar assemblages are found throughout the Andaman Islands. The reefs of the Andaman Sea are some of the most diverse in the northern Indian Ocean with 353 species reported in recent surveys in Thai waters (Turak et al., 2005). Access to the reefs of the Mergui Archipelago and the Nicobar Islands would no doubt increase this figure markedly.

Other significant facts about the corals of the Andaman Sea include their high algal densities (similar to those recorded around Singapore and in the turbid waters of Jakarta Bay) (Brown, 2007); the abundance of genera hosting Clade D algae (Pettay and LaJeunesse, 2009; LaJeunesse et al., 2010); the exceptionally high skeletal extension of the major frame builder *Porites lutea* (Scoffin et al., 1992); and the acclimatory abilities of both coral host and symbiotic algae when exposed to elevated temperatures, following their exposure to high light levels in the field (Brown et al., 2002a, b). Interestingly, recent work (Tanzil et al., 2009) has shown that over the last 19 years both linear extension rate and calcification of *Porites lutea* at Phuket, Thailand, has declined by 17.7% and 11.3% respectively, possibly as a result of rising sea temperatures which may now be beyond the coral's thermal optimum for calcification.

Despite a generally low level of human disturbance the reefs are subject to natural disturbances which include exposure to high solar radiation and desiccation when sea level is depressed; decreased salinity from heavy rain at low tide, tsunami related damage and reef subsidence and uplift through volcanic activity. Following the Asian tsunami in 2004 174 reef sites were visited within 4 days of the event along the 700km long coastline of Thailand between Myanmar and Malaysia. Results indicated minimal damage to reefs with 105 sites being unaffected or showing very little damage (i.e., 11–30% coral cover affected), while 16 sites displayed moderate damage (31–50% coral cover affected) and 23 were severely damaged (>50% coral cover affected) (Satapoomin et al., 2006). Recovery from tsunami damage in Thailand has been rapid with toppled corals showing re-orientated growth within 2–3 years of the event (Phongsuwan, 2007). Impacts in the Andamans and Nicobars were more severe with over 100 km<sup>2</sup> of shallow intertidal reef flat

being uplifted while in the Nicobars more than 200 km<sup>2</sup> of reef was damaged as a result of subsidence and sedimentation (Wilkinson, 2008). While the loss of shallow water corals was significant it should be recognised that there is a series of uplifted marine terraces evident throughout the coast of South Andaman Island with observations dating back to the mid 1800s (Bilham et al., 2005) confirming an active seismic history in the area. Reports of human damage to reefs are restricted to the Thai coastline and include tin dredging, land reclamation and associated dredging and tourism-related activities (Brown, 2007). Global warming also constitutes a serious threat to all reefs in the Andaman Sea though factors induced by climate change such as rising sea level (Church et al., 2004) and alteration of the timing of the Asian monsoon onset (Kitoh et al., 1997) might act to mitigate bleaching stresses through reduction in light levels and reduction of both temperature and light levels, respectively, at a time of year when these stresses are maximal. Little is known about the aragonite saturation state of waters in the Andaman Sea and so the susceptibility of corals to ocean acidification is, at this stage, unknown.

Interestingly, the shallow reefs around the coast of Phuket, particularly those on the outer reef edge, are currently displaying the highest cover they have ever shown in their 30 year monitoring history (Brown – pers. comm.) which may simply be a feature of steadily rising sea levels. There has also been no major bleaching and mortality since 1995 at these sites and the generally good status of these shallow reefs is also reflected at regularly monitored sub-tidal reef locations on the western coast of Thailand where reef condition is reported to have improved over recent years (Wilkinson, 2008). A recent survey of coral disease in Thai waters revealed a very low incidence of disease compared to that noted in the Caribbean and Great Barrier Reef (Kenkel, 2008).

## Summary

While the steadily rising sea temperature may be exerting an effect on coral growth rates of corals in the Andaman Sea it does appear that their history of exposure to physical rigours and resultant robust physiology may enhance their resistance to climate change. These factors, coupled with oceanographic features such as dynamic water circulation and reduced temperatures/light at critical times of the year, could lead to these turbid reefs being protected from some of the most imminent effects of global warming though the most recent mass bleaching of corals in May 2010 will prove a severe challenge to the resilience capabilities of these reefs.

## Introduction

### Background

In his coral reef book of 1842, Charles Darwin indicated that there were no coral reefs in the Eastern Tropical Pacific (ETP). Afterward, reef-building corals from the region were described (e.g., Verrill, 1870; Pourtalès, 1875; Crossland, 1927; Durham and Barnard, 1952; Durham, 1966), but the idea that there were no coral reefs in the region persisted (Stoddart, 1969) until the early 1970s when Peter W. Glynn documented coral reefs in Panamá (Glynn et al., 1972), Colombia (Glynn et al., 1982), Galápagos (Glynn and Wellington, 1983), and Costa Rica (Glynn et al., 1983). We now know that coral reefs are present in the region and many have been described, including those from México (Reyes-Bonilla, 2003), Clipperton Atoll (Glynn et al., 1996), El Salvador (Reyes-Bonilla and Barraza, 2003), Costa Rica (Cortés and Jiménez, 2003), Panamá (Maté, 2003), Colombia (Zapata and Vargas-Angel, 2003), and Ecuador (Glynn, 2003). Recently, the coral reefs of Pacific Nicaragua were studied and extensive areas located (J.J. Alvarado, personal communication 2009).

The ETP extends from the southern end of the Gulf of California, México (~23–25°N) to the Gulf of Guayaquil, Ecuador (~2–4°S) (Reyes-Bonilla, 2003; Glynn, 2003; Robertson and Cramer, 2009) (Figure 1). The region comprises eight countries with coral reefs: México, France, El Salvador, Nicaragua, Costa Rica, Panamá, Colombia, and Ecuador. The ETP has been divided into several biogeographic provinces (see review in Robertson and Cramer, 2009). Glynn and Ault (2000) divide the region into three reef-coral provinces: (1) equatorial – mainland Costa Rica to Ecuador, including the oceanic islands of Coco and Galápagos; (2) northern – mainland México and the Revillagigedo Islands; and (3) the island group – Malpelo Island and Clipperton Atoll in the ETP, and Johnston and Fanning islands in Hawaii. Based on the fish fauna, Robertson and Cramer (2009) divide the ETP into two coastal biogeographic provinces: (1) Cortez (Gulf of California and southern end of the Baja Peninsula); and (2) Panamic (central México to Ecuador); and one oceanic province, Ocean Islands: the Revillagigedo group, Clipperton Atoll, Isla del Coco, Isla Malpelo, and the Galápagos Islands. For most groups of organisms, the peak of species richness is the central Panamic province, Costa Rica, and Panamá (Guzman et al., 2004; Robertson and Cramer, 2009; Wehrtmann et al., 2009).

Coral reefs of the ETP are relatively small, discontinuous, and built by a few coral species but have a high diversity, complex food webs, and a long growth history (Guzmán and Cortés, 1993; Cortés, 1997; Glynn, 2004). They are the minimum expression of a coral reef (Cortés, 1997). In this section, I will describe the coral reefs of the ETP, starting with the climate and oceanographic setting, followed by the growth history of reefs in the region, modern-day reefs, and the main threats.

## Physical environment

### Climate

In the ETP the climate is controlled mainly by the north–south displacement of the Inter-Tropical Convergence Zone (ITCZ), a low-pressure belt just north of the equator (Alfaro, 2002; Amador et al., 2006; Alfaro, 2008). The coast of the Americas along the ETP are characterized by dry regions from México to northern Costa Rica and by wet to very wet climates from there to southern Ecuador (Taylor and Alfaro, 2005). Off-shore regions north of 10°N and south of 2°N are dry, and the oceanic islands arid. Within this region, the ITCZ moves north and south carrying high precipitations, and at around 5°N is Isla del Coco, the only oceanic island in the region with lush tropical forest (Garrison, 2005; Alfaro, 2008). The dry season in the northern ETP extends from December to April–May and it is due to the southward displacement of the ITCZ (Alfaro, 2002; Taylor and Alfaro, 2005; Amador et al., 2006).

### Hydrography

The main currents in the ETP are responsible for the prevailing oceanographic conditions and transport of

**Eastern Tropical Pacific Coral Reefs, Figure 1** Eastern Tropical Pacific coral reefs region.

organisms in the region. The strongest is the Equatorial Current, which transports waters from the eastern to the western side of the Pacific Ocean; north and south of this current are the Counter Currents, with the North Equatorial Counter Current (NECC) being the most important (Fiedler and Talley, 2006; Kessler, 2006; Lizano, 2008). The NECC is primarily responsible for the presence of Western Pacific coral species in the ETP (Cortés, 1986; Glynn and Ault, 2000).

The ETP is bounded by the California Current to the north and the Humboldt Current (aka Perú–Chile Current) to the south. Important currents within the region are the Costa Rica Current which flows along Central America from southern Costa Rica north to Mexico, bridging the Central American gap, between El Salvador and Mexico (Badan-Dangon, 1998; Kessler, 2006). The other current is the one flowing from the Panama Bight to the Galápagos Island (Rodríguez-Rubio et al., 2003; Kessler, 2006).

Environmental conditions of the central ETP are structured by the Eastern Pacific Warm Pool, a water mass characterized by high temperatures of around 27–28°C year round (Fiedler and Talley, 2006). Seasonal upwellings occur in the region, primarily at three areas where the Mesoamerican Isthmus has a low profile (Tehuantepec, México; Gulf of Papagayo, Costa Rica–Nicaragua; and Gulf of Panama, Panamá), and the Trade Winds blow across from the Intra-Americas Seas (Gulf of Mexico and Caribbean) (Alfaro and Lizano, 2001; Amador et al., 2006; Willet et al., 2006). Eddies, 150–500 km in diameter, are formed where the strong wind jets flow across the low altitude sections of Mesoamerica (Amador et al., 2006; Willet et al., 2006).

The ETP has a shallow and well-defined thermocline that ranges from 30 to 50 m depending on the region. There is also a thick oxygen-minimum layer between 300 and 700 m depth, especially around the continental shelf, where oxygen concentrations can range from near

zero to 0.5 ml of O<sub>2</sub> per liter of seawater, or <45 µmol/kg (Helly and Levin, 2004; Fiedler and Talley, 2006; Stramma et al., 2008). The pH of the region is lower compared to other tropical regions (Feely et al., 2004; Orr et al., 2005; Kleypas et al., 2006), especially during the seasonal upwellings.

El Niño-Southern Oscillation (ENSO) is an ocean-atmosphere phenomenon generated in the Eastern Pacific, with significant climatic and economic impacts worldwide (Glantz, 2001). During an ENSO event, the water temperature of the ETP rises, resulting in some cases, especially in the last two decades, in the mass mortality of corals and other marine organisms (Enfield, 1989; Glynn, 1990; Wang and Fiedler, 2006).

In summary, the ocean dynamics of the ETP depend on the large-scale ocean circulation with seasonal modifications due to wind variations and the displacement of the ITCZ. On a longer time scale, ENSO events play a significant role in the ocean dynamics and distribution of the biota of the ETP (Fiedler and Talley, 2006; Wang and Fiedler, 2006; Lizano, 2008).

## Coral reefs

### Geological history

The geological history of ETP coral reefs started after the closure of the Central American Isthmus some three million years ago (Coates et al., 1992). Before that, the waters of what is now the ETP were connected to the present day Caribbean Sea, sharing flora and fauna (Stehli and Webb, 1985; D'Croz and Robertson, 1997). The ETP is now one of the most isolated ocean regions of the world, separated from the Central Pacific by the East Pacific Barrier. This vast expanse of deep water has been an effective barrier to dispersal of tropical shallow-water organisms throughout the Cenozoic (Cortés, 1986; Grigg and Hey, 1992; Glynn and Ault, 2000). The main currents in the ETP are from east to west, the north and south Equatorial Currents (Glynn et al., 1996; Fiedler and Talley, 2006; Lizano, 2008). However, the weaker but nevertheless important North Equatorial Countercurrent can transport organisms to the Eastern Pacific from the Central and Western Pacific (Scheltema, 1988; Richmond, 1990; Glynn et al., 1996).

After the closure of the Central American Seaway, all Caribbean reef-building corals in the ETP became extinct and were substituted by Indo-Pacific species (Dana, 1975; Cortés, 1986; Glynn, 1997). At present, there are five genera shared but not a single species of reef-building corals in common between the Caribbean and the ETP (Cortés, 2003). Other marine groups in the ETP also show this Indo-Pacific affinity, including mollusks (Scheltema, 1988), echinoderms (Lessios et al., 1998), and fishes (Robertson and Cramer, 2009).

With the closure of the Central American Seaway, oceanographic conditions profoundly changed in the ETP (D'Croz and Robertson, 1997). Now, El Niño could develop bringing warm waters to the region (Enfield, 1989), and the seasonal upwellings off the low lands of

Mesoamerica bring cold waters to the region (Glynn et al., 1983; Willet et al., 2006). The ETP is also a pocket of low-salinity and low-pH waters as compared to other oceans (Fiedler and Talley, 2006; Kleypas et al., 2006; Lizano, 2008). All these conditions are inimical for reef development and consolidation (Cortés, 1997; Manzello et al., 2008). Additionally, there were significant changes to oceanic circulation with the closure of the Central American Isthmus.

The continental shelves of ETP are narrow and drop abruptly to a deep seafloor with some seamounts and ridges (e.g., Carnegie and Cocos). The narrowness of the shelf contributes to the limited development of coral reefs in the region. Cortés (1986) suggested that during the low sea level stands in the Holocene significantly reduced the area where coral reefs could develop. This, combined with the changing oceanographic conditions in the ETP after the closure of the Central America Seaway, resulted in the elimination of most coral reefs in the region and allowed subsequent replenishment from the Western Pacific.

### Holocene growth history

Extant coral reef growth in the ETP started around 5,600 years BP (Glynn and Macintyre, 1977; Cortés et al., 1994). In Panamá, the dominant reef-framework builders are pocilloporid corals, mainly *Pocillopora damicornis*. Reef growth ranges from 1.3 to 4.2 m/1,000 years in the reef flat to 7.5 m/1,000 years in the reef front. Mean maximum reef thickness was higher in the non-upwelling region (Gulf of Chiriquí: 8.3 m, with a maximum of 13 m) than in the upwelling Gulf of Panama (4.2 m) (Glynn and Macintyre, 1977).

At Punta Islotes in Golfo Dulce, Costa Rica, the initial phase of reef growth was by pocilloporids, which created a substrate over sandy bottoms on which *Porites lobata* grew, the dominant reef-frame builder in this location. During the first 3,000 years, growth was slow, but between 2,500 and 500 year BP reef structure growth was extremely fast, in the order of 5–8.3 m/1,000 years, attaining reef framework thickness of up to 9 m (Cortés et al., 1994). At around 500 year BP, there was a significant increase in fresh water in Golfo Dulce. Tectonic movements altered the watersheds, and two large rivers started flowing into the inner section of the gulf where the reefs were growing (Cortés, 1990). This slowed reef accretion, and about 60 years ago reef growth completely stopped when there was an increase in terrigenous sedimentation as a result of the removal of the forest for banana plantations. Sediments loads are still high due to deforestation, inappropriate agricultural practices, coastal alteration, and road construction in the gulf's watershed.

Coral reef growth off the coasts of Panamá and Costa Rica has resulted in thick reef structures (up to 13 m), while in offshore islands (Isla del Caño and Isla del Coco, Costa Rica; and the Galápagos Islands, Ecuador) the reef framework is only a thin veneer of corals over

non-carbonate substrates (Macintyre et al., 1992). The relief of the reef structure is inherited from the non-carbonate substrate, with some large massive corals present. At Isla del Caño, the oldest framework was 2,000 year BP, while at Isla del Coco and the Galápagos Islands samples from the base of the largest *Porites* colonies yield dates of between 320 and 450 years BP (Macintyre et al., 1992).

Postdepositional alteration of corals is minimal in the ETP (Glynn and Macintyre, 1977; Cortés et al., 1994), as is subsequent reef consolidation (Cortés, 1997; Manzello et al., 2008). This may be due to the rapid accumulation rates, lack of high turbulence, and, in general, low pH of the surrounding waters (Glynn and Macintyre, 1977; Cortés, 1997; Manzello et al., 2008). These reefs are subject to rapid bioerosion (Cortés, 1997; Fonseca et al., 2006), resulting in very few examples of exposed Holocene reefs (Glynn and Wellington, 1983; Denyer and Cortés, 2001). ETP reefs are very fragile and, in general, are obliterated before preservation (Cortés, 1993). Branching corals are uncemented, and massive colonies are usually highly bioeroded and in many places unattached to the substrate (Scott and Risk, 1988; Fonseca, 1999). Reef framework is also bioeroded, especially once the coral dies (Glynn et al., 1979; Glynn, 1988; Colgan, 1990; Glynn and Colgan, 1992; Eakin, 1996; Reaka-Kudla et al., 1996; Fonseca et al., 2006). In conclusion, reef preservation is very low in the ETP (Cortés, 1997).

### Types of coral reefs

There are at least 35 species of zooxanthellate corals in the ETP (Reyes-Bonilla, 2002), but only three are important reef builders across the entire region (*Pocillopora damicornis*, *P. elegans* and *Porites lobata*). *Pocillopora* spp. reefs are found in México (Reyes-Bonilla, 2003), Costa Rica (Cortés, 1996/1997; Cortés and Jiménez, 2003), Panamá (Maté, 2003; Guzman et al., 2004, 2008), Colombia (Glynn et al., 1982; Zapata and Vargas-Ángel, 2003), and the Galápagos Islands (Glynn and Wellington, 1983; Glynn, 2003). *Porites* reefs are found at Clipperton Atoll (Glynn et al., 1996), in Costa Rica (Cortés and Jiménez, 2003), and in some areas of the Galápagos Islands (Glynn and Wellington, 1983; Glynn, 2003). Other species that are important as reef builders in particular localities are *Pocillopora eydouxi* in Colombia (Glynn et al., 1982), Panamá (Guzmán et al., 1991), and Costa Rica (Cortés, 1996/1997); and *Pavona clavus*, *Psammocora stellata*, and *Leptoseris papyracea* in Costa Rica (Cortés, 1990; Jiménez, 2001; Bezy et al., 2006).

Coral communities that increase structural heterogeneity on sand/rubble or rocky surfaces are very important in the ETP. In some areas, they may be important contributors to the local benthic ecology of non-reefal habitats. These coral communities can be formed by scattered colonies of the main reef builders growing over basalts or sand/rubble, as in Bahía Culebra, Costa Rica (Jiménez, 2001), or by non-reef-building corals, e.g., *Diadema*

*distorta* and *Psammocora stellata* in deep reefs in the Galápagos Islands (Feingold, 1995, 1996); and *Diadema distorta* and *Porites sverdrupi* in the Gulf of California (Feingold et al., 2009).

In many regions, the predominant reef builders in shallow waters are pocilloporids, while in deeper waters the main reef builders are *Porites lobata* and *Pavona* spp., for example, in Panamá (Glynn et al., 1972), Galápagos Islands (Glynn and Wellington, 1983), and Costa Rica (Guzman and Cortés, 1989; Cortés, 1990; Guzman and Cortés, 2007). The shallow reefs in the ETP are physically controlled by wave action and low tidal exposure, while deeper sections are biologically controlled mainly by predation and competition (Glynn, 1976; Guzman and Cortés, 1989).

### Threats/impacts

#### El Niño-Southern Oscillation (ENSO)

ENSO events are atmospheric-oceanographic phenomena which in the ETP manifest themselves as warming episodes with devastating consequences to corals and coral reefs (Glynn, 2000). These warming events have caused the most damage to coral reefs in the entire ETP. The first major recorded event was during the 1982–83 El Niño, causing coral mortalities ranging from 50 to 99% (Glynn, 1984). Glynn et al. (1988) determined that the greater the temperature anomaly, the longer the warming event, and the faster the warming increased, the more was the impact on the coral communities and reefs. Subsequent warming events associated with ENSO, especially the 1997–1998 event, also caused significant impacts (Glynn and Colley, 2001). All regions of the ETP have been affected: México (Reyes-Bonilla, 2003), Costa Rica (Guzman and Cortés, 2001; Jiménez and Cortés, 2001; Jiménez et al., 2001; Jiménez and Cortés, 2003; Guzman and Cortés, 2007), Panamá (Glynn, 1990; Maté, 2003), Galápagos, and mainland Ecuador (Glynn, 2003). Recovery has been observed in some areas but it has been slow (Guzman and Cortés, 2001; Guzman and Cortés, 2007).

#### Subaerial exposure

Extreme low tides have been observed in the ETP and have limited local effects, but significant for reef flats depending on the season and time of day. These exposures of the shallow reef may be due to extremely low astronomical tides and ENSO-related sea-level drop (Glynn, 1984; Eakin and Glynn, 1996). Exposure of corals have been illustrated from Panama (Eakin and Glynn, 1996; Maté, 2003) and Ecuador (Glynn, 2003).

#### Sedimentation

The presence of terrigenous sedimentation in coral reefs is a major cause of reef deterioration worldwide (Fabricius, 2005). Excessive amounts will bury and kill corals, while low concentrations also have negative effects. The corals must spend energy to clean themselves by ciliary action, polyp expansion, and/or mucus sheet production all with

an energy cost – energy that cannot be used for growth, reproduction, resistance to diseases, or wound repair (Cortés and Risk, 1985; Rogers, 1990; Fabricius, 2005).

In the ETP, the impact of sediments have been studied in Mexico (Ochoa-López et al., 1998; Granja-Fernández and López-Pérez, 2008), Costa Rica (Cortés, 1990; Alvarado et al., 2009), Colombia (Zapata and Vargas-Ángel, 2003), and Ecuador mainland (Glynn, 2003). In some areas, for example, Golfo Dulce in southern Costa Rica, terrigenous sedimentation resulted in the cessation of reef growth (Cortés et al., 1994).

### Organism extraction

The impact of reef organisms extraction has not been studied in detail. In several countries in the region ornamental fishes are extracted for the aquarium trade with no or very limited control (McCauley et al., 2008; <http://www.aquariumcouncil.org>). Corals and octocorals are also extracted for the curio trade in El Salvador (personal observation), Costa Rica (Cortés and Murillo, 1985), Colombia (Zapata and Vargas-Ángel, 2003), and Ecuador (Glynn, 2003). Panama is the only country in the region with laws that prohibit the extraction of live or dead coral (Maté, 2003), as is also in the Galápagos Islands (J. S. Feingold, personal communication).

### Climate change

Climate change is now considered one of the main threats to coral reefs worldwide (Hughes et al., 2003; Hoegh-Guldberg et al., 2007; Hughes et al., 2007; Baker et al., 2008). Sea water warming and associated bleaching is the most obvious impact on corals reefs, resulting in reduction in growth rates, reproductive output, recruitment/survivorship of larvae, competitive abilities, capacity to regenerate tissue, increased susceptibility to diseases/stress, and partial/total mortality of the colony. There can also be changes in the structure and functioning of coral populations and reef communities, and phase shifts to different group/species community composition (Baker et al., 2008; McClanahan et al., 2008). A not so obvious consequence of the accumulation of CO<sub>2</sub> in the atmosphere is ocean acidification (Kleypas et al., 2006; Hoegh-Guldberg et al., 2007), and this may be the main threat to the existence of coral reefs in the future. This problem is especially exacerbated in the ETP, since pH in the region is lower than other oceans, and drops even more during the upwelling periods.

### Coral reef resilience

Resilience is generally defined as the ability of a coral reef to return to a previous state after some perturbation (West and Salm, 2003; Nyström et al., 2008). Several characteristics of coral reefs are recognized as important to maximized resilience: these include maintaining a healthy herbivore community, high biodiversity, inter-reef and inter-system connectivity, and reduced human impact (Hughes et al., 2005; Mumby and Hastings, 2008;

Nyström et al., 2008). Speed of recovery and resilience of coral reefs is greater in areas with less human activity.

### Conclusions

ETP coral reefs are constructed by just a few species of reef-building corals, yet they are highly complex in interspecies interactions (Cortés, 1997; Glynn, 2004). As carbonate structures, they started growing shortly after rising sea level flooded appropriate substrates over 5,000 years ago, but the frameworks are fragile, with little cementation, and are easily bioeroded. For this reason, there are practically no examples of exposed Holocene fossil reefs in the region as is so common on the Caribbean. These coral reefs are widely distributed from southern Baja California to Ecuador, including offshore islands, with a similar suite of reef-building corals (*Pocillopora* spp., *Porites lobata* and *Pavona* spp.), even though they range from extreme dry regions to very humid and from upwelling to nonupwelling areas. The main impact on ETP coral reefs have been El Niño warming events; other disturbances include cooling events, subaerial exposure, excessive terrigenous sedimentation, organisms extraction, and climate change, among others. The corals in this region were significantly impacted by the 1982/83 El Niño and then again by the 1997/98 event, but most reefs are recovering, though slowly. Coral reef resilience must be maximized by maintaining a healthy herbivore community, high biodiversity, inter-reef and inter-systems connectivity, and reduced human impact.

## ECHINODERMATA

Maria Byrne  
 University of Sydney, Sydney, NSW, Australia

## Definition

Echinodermata is defined as a phylum of marine invertebrates with a spiny skin and radial symmetry.

## Introduction

Echinoderms are a conspicuous and diverse component of the invertebrate fauna of coral reefs and include

species from five extant classes Asteroidea (sea stars), Ophiuroidea (brittlestars), Echinoidea (sea urchins), Holothuroidea (sea cucumbers), and Crinoidea (feather stars). They have a distinct radial symmetry based on pentamery. There are usually five radii (e.g., arms of sea stars), although multiarmed (6+ arms) asteroids and brittle stars are common. Asteroids are star shaped with the arms (five or more) tapering from the disc (e.g., *Linckia*) or a cushion-like pentagon shape lacking arms (e.g., *Culcita*). Ophiuroids have a round central disc and slender flexible arms that are sharply set-off from the body. Their body can have a simple (brittle stars or serpent stars) or branched (basket stars) profile. Echinoids have a rigid globose body covered by spines. Holothuroids are elongate sausage-shaped. Crinoids have an array of feather-like arms that range in number from five to more than two hundred.

Echinoderms are an ecologically important component of coral reef ecosystems. They are often the dominant organisms on the sea floor. In shallow and intertidal coral reef environments, this is particularly true of sea cucumbers (e.g., *Holothuria*) on reef flats and sandy areas. Several ecologically important keystone echinoderm species exhibit boom and bust cycles in population density, including sea urchins (*Diadema*) and the crown of thorns sea star (*Acanthaster planci*) (see section). Echinoderms provide crucial ecological services to reef systems, with roles in nutrient cycling, predation, water quality regulation, and herbivory.

Most tropical sea cucumbers are benthic deposit feeders in soft sediment inter-reefal and lagoon environments, where they provide important ecosystem services. They enhance the productivity of nutrient poor carbonate sediments through their bioturbation, burrowing, and feeding/digestive activity. Taxonomically, these sea cucumbers have long been a challenge, a problem of concern for the management of poorly known commercial beche de mer species, many of which are now locally extinct due to overfishing.

Most sea urchins are grazers using their hard teeth to remove algae and encrusting organisms from the surface. As a member of the grazing guild on coral reefs, sea urchins contribute to keeping the biomass of algae low, thereby preventing the overgrowth of algae over coral substrate. Loss of urchins, such as the disappearance of *Diadema* in the Caribbean in the 1980s, resulted in an ecological shift from coral to algal dominated reefs. *Tripteneustes gratilla* a commercially important tropical sea urchin is a specialist on sea grass. The burrowing activity of echinoids, particularly *Echinometra* species, is important in bioerosion of coral reef and intertidal habitats.

Crinoids and many ophiuroids are suspension feeders extending their arms above the substrate to capture food particles on their small tube feet that line the arms. The food is captured from flow, and so they take up positions on the reef to take advantage of ambient water movement.

Food particles are conveyed to the mouth in the centre of the disc by food tracts. Some ophiuroids are predators and scavengers.

## Conclusion

Echinoderms are key members of the biodiversity of coral reef ecosystems. Some species, such as *Acanthaster*, *Diadema*, and *Echinometra*, are particularly important in structuring coral reef communities. Some sea urchins and many sea cucumbers are important as fishery species.

## ECO-MORPHODYNAMICS

---

Paul Kench

The University of Auckland, Auckland, New Zealand

## Definition

Eco-morphodynamics is the interaction and co-adjustment of coral reef structure, morphology, and physical hydrodynamic and ecological processes that is mediated by the production, transfer, and deposition of calcium carbonate.

## Introduction

Coral reefs and reef sedimentary landforms are unique in that they are composed predominantly of calcium carbonate (CaCO<sub>3</sub>) that is generated almost entirely from ecological processes. Reef scientists have long recognized the fact that the structure of coral reefs reflects a balance between the constructive processes of framework building corals and other primary and secondary carbonate

producers, and the destructive processes of mechanical wave action and bioerosion (e.g., Darwin, 1842; Scoffin, 1992). Initially, the recognition of these dynamics underpinned explanations of the presence and gross structure of coral reefs and they have been modeled using a carbonate budget approach (Perry and Hepburn, 2008; Perry et al., 2008). The by-products of reef growth and destruction (detrital sediment) can also lead to landform construction and change. For instance, reef islands rely on production and transfer of detrital sediment from a contiguous reef system, although they have typically been regarded as losses to the reef sediment budget (Scoffin et al., 1980; Hubbard et al., 1990; Kleypas et al., 2001). Over the past century, an expansion of research to describe and account for other morphological features on and adjacent to coral reef structures has recognized that the balance of constructive and destructive processes on reefs operates at a range of space and time scales. Variability in that balance (e.g., in extent, rates, duration, timing) produces a wide range of macro- to micro-scale geomorphic units, from entire reef platforms to a particular spur and groove morphology.

Physical processes that mechanically erode, transport, and deposit calcium carbonate are of paramount importance in controlling the distribution, structure, and morphology of reefs and sedimentary landforms (Scoffin et al., 1980). Once a reef is constructed, feedbacks that modify microenvironments and process interactions that drive the distribution of ecological communities and morphological products exist. The term “eco-morphodynamics” was recently introduced by Kench et al. (2009) as a conceptual framework to provide a more detailed exploration of the complex relationships that exist between ecological and physical processes and reef geomorphology.

### Morphodynamic origins

Eco-morphodynamics is an extension of the morphodynamic concept, which has been widely used by geomorphologists to account for the co-adjustment of landforms and processes in coastal environments (Wright and Thom, 1977; Cowell and Thom, 1994). Typically applied in siliciclastic coastal settings, a morphodynamic approach accounts for hydrodynamic processes and their interaction with seafloor and coastal features to drive morphological adjustment involving the movement of sediment. Hydrodynamic processes include waves, tides, and wind-induced currents. While these processes respond instantaneously to morphology, morphological change itself is slower, requiring the redistribution of sediment. As sediment takes a finite time to move, there is a lag in the morphological response to hydrodynamic forcing. Therefore, sediment can be considered to be a time-dependent coupling mechanism. Unique to coral reef systems, the sediment reservoir is produced solely by ecological processes that produce calcium carbonate. Furthermore, different coral reef settings (locations; geomorphic

zones) vary greatly in the rates at which they produce calcium carbonate (Kinsey, 1983). Consequently, the carbonate factory is a highly space- and time-dependent coupling mechanism. However, the time dependency of reef geomorphology to the carbonate factory emerges not only from the temporal lags in redistribution of material but also from the timeframes associated with organism growth, mortality, and conversion to detrital sediment (Perry et al., 2008). The influence of such temporal lags on morphological change in reef systems is poorly understood.

### Eco-morphodynamic framework

The structure and function of the eco-morphodynamic framework of a coral reef system is presented in Figure 1, which clearly shows the importance of carbonate cycling. Examination of this framework highlights a number of implications for the co-adjustment of physical processes, reef ecological communities, and geomorphic products.

### Boundary controls

Alterations in boundary controls will force change in coral reef system state (ecological, physical, and geological characteristics). Such changes in boundary conditions can occur as a consequence of extrinsic changes in the atmosphere–ocean system such as sea-level rise, ocean temperature, and chemistry variations (Hoegh-Guldberg, 1999; Kleypas et al., 2001; Buddemeier et al., 2004; Orr et al., 2005; Kench et al., 2009). Changes in the intrinsic factors (e.g., physical and ecological processes) can also force dynamic change in reef systems. These intrinsic linkages are themselves impacted by anthropogenic activities such as over-exploitation of physical and biological resources and coastal construction (Browne and Dunne, 1988; Jackson, 2001; Hughes et al., 2003; Lidz and Hallock, 2000; Sheppard et al., 2005).

### Time and space scales of change

The magnitude, mode, and timeframes of change (responsiveness) in the system are likely to vary considerably between different components of a reef system. Examples include the following:

- (i) Development of coral reef platforms, which are known to be modulated by sea-level oscillations at millennial timescales (Kennedy and Woodroffe, 2002; Montaggioni, 2005)
- (ii) Reef island development, which is a function of a reef basement, sediment supply, and process regime, occurring at centennial timescales (Woodroffe, 2003; Kench et al., 2005)
- (iii) Shoreline dynamics of reef islands, which occur at event to decadal timescales in response to alterations in wave energy input (Maragos et al., 1973; Flood, 1986; Kench and Brander, 2006a)
- (iv) Ecological transitions that can occur at event to decadal timeframes in response to extreme climatic events or changes in ocean temperature, ocean

**Eco-Morphodynamics, Figure 1** Structure and function of the eco-morphodynamic model for the coral reef system. The model shows co-adjustment of biological and physical processes, and coral reef morphology and reef sedimentary landforms that operate at a range of timescales. *Gray shaded boxes* and *dark arrows* highlight linkages between the contemporary eco-morphodynamic systems controlling sedimentary landform development at event- to centennial scales, which are embedded in the broader morphodynamic system that controls coral reef development at centennial to millennial scales. (After Kench et al. [2009]).

chemistry, or water quality (Woodley et al., 1981; Done, 1992; Hughes et al., 1994; Eakin, 1996)

### Feedbacks

There are eco-morphodynamic feedbacks that are temporally specific and those that cascade across timescales. Both provide a degree of self-organization to geomorphic development. For instance, at millennial timescales sea-level change controls the patterning of reef growth. In turn, the reef structure modulates wave and current processes (Gourlay, 1988; Symonds et al., 1995; Kench and Brander, 2006b) that govern the structure of ecological

communities (Chappell, 1980; Done, 1982), reef morphology (Yamano et al., 2003), sedimentation processes, and short-term morphological development of reef-associated landforms (Sheppard et al., 2005).

The eco-morphodynamic framework also indicates that feedbacks are non-linear with significant time lags existing for changes to propagate through the geomorphic system. For instance, ecological transitions may occur in response to short-term bleaching episodes, anthropogenic stress or biological disease (Liddell and Ohlhorst, 1993; Eakin, 1996). Depending on the magnitude of change in the ecological system (e.g., the severity and spatial extent of coral mortality and the rate of recolonisation by corals),

the carbonate factory may alter its sediment budget status over decades (Perry et al., 2008). Ultimately, depending on the magnitude and temporal scale of ecological change (persistence or ephemeral transition), alterations in the carbonate budget may, or may not, propagate through the system to yield detectable changes in the geomorphic system at decadal to centennial timeframes (Kench et al., 2009).

## Summary

The formation and morphological adjustment of coral reefs and reef sedimentary landforms results from the dynamic interaction between biological and physical processes, which operate at a range of time and space scales. Eco-morphodynamics is a conceptual framework that identifies the major process response linkages between physical and biological processes which are responsible for the spatial and temporal dynamics of ecological communities, physical processes, and geomorphology (Figure 1). Central to the framework is the importance of the coral reef “carbonate factory” in providing the building blocks (skeletal material, sand, and gravels) for construction of reef landforms. The framework also highlights the multiple extrinsic and intrinsic factors that promote change in ecological, physical, and geomorphic processes and products in reef systems.

Eco-morphodynamics provides a conceptual framework to explore: the sensitivity of landforms to perturbations in boundary conditions; thresholds and timescales of change; and feedbacks, temporal lags, and nonlinearities in the linkages between the physical, ecological, and geological components of reef systems. Currently, these system sensitivities, thresholds, temporal lags, feedbacks, and timescales of relevance to reef geomorphic development and change are poorly resolved.

## ECOMORPHOLOGY

Colin D. Woodroffe  
University of Wollongong, Wollongong, NSW, Australia

## Definition

Ecomorphology describes the interrelationship between coral growth form and the dominant environmental factors that influence reefs. It derives from a growth-form response that was suggested by John Chappell in 1980.

## Introduction

A coral reef comprises a limestone substrate across which various organisms are distributed, competing for, and partitioning, space in response to a series of environmental factors, such as light, sediment and wave energy. These factors vary across the reef and represent stresses to which organisms such as the corals respond. The various corals, adopting distinct growth-forms, have discrete tolerances and their distribution appears related to environmental gradients in these stresses. An ecomorphological zonation based on these principles was outlined by Chappell (1980).

## Environmental stresses and their effect on corals

Chappell (1980) hypothesized growth-form responses in corals to four gradients in environmental parameters. Figure 1 is indicative of the sort of responses that he envisaged. (1) Light response: corals require light in order that their symbiotic zooanthellae can photosynthesize, and where light is abundant growth forms can support extensive polyp-covered surfaces in comparison with their projected surface area. Digitate plate and compound plate morphologies can occur near the water surface where light is abundant, being replaced by corals with less polyp-covered surface at greater depth (Figure 1). (2) Hydrodynamic stress: delicate forms of coral are fractured if wave energy is high, and only more robust forms with greater structural strength can persist where wave energy is greatest. (3) Sediment flux effect: although recent research indicates that reefs can support diverse coral communities in some turbid settings, sediment can smother polyps and limit growth. Platy growth forms are more prone to smothering than those that do not have extensive horizontal surfaces. (4) Subaerial exposure: at lowest tides, exposure of coral polyps exerts a stress on corals. Flat-topped microatolls (discoid corals that are living on the margins but dead on top) and encrusting forms are best adapted to such exposure.

## Variation in coral communities across a section of reef

Wave energy is one of the most important controls on reefs and has received considerable study. Corals are often well-developed where wave energy is high, although the most exposed reef crests are generally dominated by coralline algae, often forming a distinct rim. Wave energy is a function of wave height squared and decreases with depth down the reef front. Fragile branching corals are prone to breakage and can only survive where wave energy is low; they are replaced by structurally stronger corals, such as globose or encrusting forms in higher wave-energy settings (Figure 1).

Corals also have to cope with a range of light conditions; for instance, the massive West Indian coral *Montastrea annularis* changes its form, becoming flatter and more platy with depth down a reef front. Platy corals are poorly-adapted to tolerate high sediment loads;

**Ecomorphology, Figure 1** Ecomorphological zonation on a reef, showing characteristic generalized growth forms, in response to light, sediment and wave stress and subaerial exposure (after Chappell, 1980. Reprinted by permission from Macmillan Publishers Ltd: Nature, 1980).

ramose, branching and foliate corals are much better able to cope with high sediment loads and are more common where turbidity is high.

Figure 1 shows a schematic model of coral growth-forms in relation to environmental gradients proposed by Chappell (1980). On the basis of this model growth forms are dominant at different points across the reef profile and hypothetical diversity curves are also derived, ranging from a maximum when environmental stresses are minimal, to zero where any stress is limiting. The reef front is likely to have massive forms at depth. Towards the reef crest more sturdy branching forms of coral will occur, and the branches may be oriented into the dominant wave direction. In the highest wave-energy settings corals will be encrusting, or may be replaced by encrusting coralline algae as occur on the algal ridges of Indo-Pacific reefs.

### Applications of the model

The ecomorphological patterning proposed by Chappell (1980) would suggest that the dominant growth forms of corals vary across reefs. Zonation of organisms has been widely observed on reefs, and such studies formed a basis on which Chappell developed his schema. They also suggest that the processes vary, and of the major environmental factors much research has focused on wave

energy and its variation across reefs. Light is a limiting factor at depth on a reef. At intermediate depths on a reef intricately branching corals can survive, but these are replaced in the zone where waves break by more robust corals, with encrusting forms dominating the reef crest (Hopley, 2008). Subaerial exposure imposes a stress on many reef flats and several coral genera may adopt a microatoll growth morphology as a result of exposure at low tide.

Chappell (1980) considered that this ecomorphological zonation could be used to simulate reef growth, assuming that growth of coral framework is constrained by the four factors such that there is diminished growth as net stress increases and growth ceases when any factor becomes limiting. The model was compared with the overall morphology of fossil reefs on the Huon Peninsula of northern Papua New Guinea, and the taphonomy of coral growth-forms was also an indication of the depth and habitat conditions that had characterized those fossil reefs. The approach has also been found useful for deciphering former habitats in other uplifted Pleistocene reefs on island arcs in the region, and applied in a more restricted way to the less diverse fossil reefs of the Caribbean. The approach has also been of value in interpreting much older fossil reefs, of Cainozoic, Mesozoic and even Paleozoic age, and has been applied in stratigraphic models.

## Summary

Zonation is apparent on many coral reefs and coral growth form reflects environmental gradients in several factors, particularly light availability, wave energy, emersion, and sedimentation patterns.

## EL NIÑO, LA NIÑA, AND ENSO

---

Joshua S. Feingold  
 Nova Southeastern University, Dania Beach,  
 Florida, USA

## Synonyms

La Niña is also called Anti-El Niño and El Viejo

## Definition

El Niño (The Christ child) is a seasonal current that typically transports warm sea surface water from the Pacific coast of Central America to the equatorial Eastern Pacific. Also, it refers to the migration of Central Pacific equatorial warm water to the east, and the warm phase of the Southern Oscillation.

La Niña (The little girl) is the cool phase of the Southern Oscillation.

El Niño-Southern Oscillation (ENSO) is the coupled ocean-atmospheric shifts in high pressure centers from the equatorial Western Pacific to the equatorial Eastern Pacific.

## Introduction

El Niño, La Niña, and El Niño-Southern Oscillation (ENSO) are related but distinct phenomena. The El Niño current is a seasonal, warm current that typically originates near Central America and flows into sea surface waters off Ecuador and Peru. This current typically appears in late December or early January, and its association with Christmas and the Epiphany led to it being called El Niño (The Christ Child). Central Pacific equatorial warm water that

migrates to the east also produces warming of the Eastern Pacific, and has been called El Niño. The term El Niño is also used to denote the warm phase of ENSO, with La Niña referring to the cool phase (Philander, 1990). ENSO results from a wide scale shift in pressure centers related to feedback cycles within the coupled ocean-atmosphere climate system of the tropical Pacific, potentially influenced by external forcing (Enfield, 1989). During the ENSO warm phase, high atmospheric pressure, typically located in the West Pacific (near Darwin, Australia), shifts to the Central Pacific (near Tahiti), reducing westerly trade wind velocities, and consequently reducing the flow of the South Equatorial Current. Tropical heat that is normally pumped to the west by this current is retained in the Eastern Pacific. Under extreme warm phase ENSO conditions, wind fields reverse and easterly winds move warm surface water into the Eastern Pacific. Kelvin Waves are also associated with Eastern Pacific warming, as they pump subsurface warm water to the east along the equator. Persistence of high pressure in the Central Pacific indicates El Niño conditions, and especially high pressures in the Western Pacific associated with colder Eastern Pacific sea-surface water are indicators of La Niña. The cool phase of ENSO (La Niña) can follow the warm phase as global pressure shifts relax towards normal and occasionally overshoot, resulting in anomalously cool conditions in the eastern tropical Pacific (Enfield, 2001).

Links between ENSO and global climate perturbations have been documented (Holland, 2009), and related impacts to adjacent regions (teleconnections) affect coral ecosystems in the western Caribbean Sea (Coffroth et al., 1990), Indian Ocean (Wilkinson et al., 1999), Indonesia (Brown and Suharsono, 1990), French Polynesia (Hoegh-Guldberg, 1999), and even coral reefs worldwide (Wilkinson, 2000).

ENSO events have occurred every  $3.8 \pm 1.8$  (mean  $\pm$  s.d.) years, and strong and very strong events every  $9.9 \pm 4.2$  years (Enfield and Cid, 1991). No two ENSO events are alike. Their strength is related to the intensity and duration of sea-surface temperature (SST) anomalies (differences between measured temperatures and long-term means). Two very strong events occurred in 1982–1983 and 1997–1998. The event in 1982–1983 was called the strongest of the twentieth century (Kerr, 1983), at least until the 1997–1998 event which was comparable in magnitude (Enfield, 2001). Conditions are now (August 2009) favorable for the development of another ENSO in 2009–2010 (NOAA, 2009).

The strength of the event is generally proportional to the amount of impact to coral. Weak to moderate ENSO events have had little effect, whereas the severe events of 1982–1983 and 1997–1998 resulted in coral mortality ranging from 15 to 99% at locations in the tropical Eastern Pacific (Glynn, 2001).

## ENSO effects on corals

ENSO effects on corals were first well documented during the 1982–1983 event, and even more thorough investigations were performed during the 1997–1998 event

(Glynn, 2001). Sea-surface perturbations associated with the warm phase of ENSO have the strongest effect on corals in the eastern tropical Pacific (Glynn et al., 2001); however, corals in the Central and Western Pacific (Hoegh-Guldberg, 1999), Indian Ocean (Wilkinson, 2000), and Caribbean Sea (Coffroth et al., 1990) are also affected. These perturbations include elevated SSTs, elevated sea level, depressed main thermocline, diminution and reversal of surface and subsurface currents, increased wave assault, decreased nutrients and productivity, and increased rainfall (and concomitant increased sedimentation in nearshore environments) (Philander, 1983; Fiedler et al., 1992). During ENSO cool phase (La Niña), corals in the Eastern Pacific are exposed to opposite conditions; depressed SSTs, lower sea level, elevated main thermocline, intensification of westward-flowing currents, normal wave action, increased nutrients and productivity, and decreased rainfall.

### SST anomalies and coral mortality

Sea-surface warming associated with ENSO is implicated as the primary cause of coral bleaching and mortality (Glynn et al., 1988; Glynn and D'Croz, 1990). Thermal impacts are more related to temperature anomalies (differences from long-term mean temperatures) than absolute temperature. For example, during the 1982–1983 ENSO, mean coral mortality was higher in the Galapagos Islands (99%) than in Costa Rica (51%) even though mean monthly SSTs were lower (28.5 vs. 31°C). Temperature anomalies ranged from +3 to +4°C in the Galapagos Islands where corals were strongly affected, compared to +1 to +2°C in Costa Rica (Glynn, 1990). In the Indian Ocean, temperatures 3–5°C above normal were reported, and mortality up to 90% in shallow habitats was observed (Wilkinson et al., 1999).

Though less well studied, cooling can also stress corals, resulting in mortality. Populations of *Pocillopora* at Devil's Crown, Galapagos Islands, were reduced by approximately 85% following exceptionally cool conditions in 2007 (Feingold, unpublished data). Bleaching and mortality were reported in Costa Rica during cooling associated with a 1985 La Niña event (Guzmán and Cortés, 2001).

Combined effects of ENSO can result in regional-scale extirpation of corals and dramatic change to reef communities. Reductions of corals and subsequent bioerosion of reef framework in the Galapagos Islands have eliminated the few reefs that occurred there (Glynn and Ault, 2000).

### Coral bleaching

ENSO-related coral bleaching occurs when endosymbiotic dinoflagellates (zooxanthellae) either diminish in number within the coral host tissues, or lose their photosynthetic pigment. Since zooxanthellae are an important source of energy, reef-building corals will die unless sufficient populations of the endosymbiont become re-established. Bleaching severity shows species-specific trends, with some corals being sensitive (e.g. *Pocillopora*) and others resistant (e.g. *Psammocora*) (Glynn, 1990). Bleaching

occurs when coral is physiologically stressed, and is most often associated with positive SST anomalies (warming), although other perturbations such as cooling, lower sea level, salinity decrease, and sedimentation contribute.

Bleaching sensitivity is also related to the endosymbiont clade; some zooxanthellae are more tolerant to elevated temperatures than others. For example, in Panama, pocilloporid corals with zooxanthellae in clade D did not bleach, whereas those with clade C did (Baker, 2004). Thus, coral survivors of the 1982–1983 ENSO predominantly harbored clade D endosymbionts, and when these corals were exposed to highly elevated temperatures again in 1997–1998, they were not as severely affected as they were in 1982–1983 (Glynn et al., 2001).

Sea level decrease also results in coral bleaching and mortality, particularly severe when combined with spring low tides. Sea level is low in the west during ENSO warm phase, and low in the east during ENSO cool phase (La Niña). For example, reef flats were exposed in Guam during warm phase ENSO in 1972–1973 (Yamaguchi, 1975), and corals were affected in French Polynesia and the Tokelau Islands during the 1982–1983 and 1993 events (Coffroth et al., 1990). La Niña conditions in 1989 and 1993 resulted in sub-aerial exposure of coral on the reef flat and high coral mortality at Uva Island, Panama (Eakin, 2001).

### Mitigation by depth and light

Coral reefs and coral communities are more common in shallow waters (<10 m depth) where positive temperature anomalies are strongest. However, corals also live in deeper water where sea-surface warming is not so pronounced. In the Eastern Pacific, corals living >15 m in depth were not so strongly affected by ENSO-related warming (0% mortality) as those in shallow waters, due to periodic shoaling of cooler water from the subsurface mixed layer (Feingold, 1996). Wilkinson et al. (1999) reported less coral mortality at depths >20 m (50%) compared to shallower habitats (90%) in the Indian Ocean. Lower levels of light at deeper depths may contribute to lessening impacts, since combined effects of elevated levels of light and temperature together are more detrimental to corals than either one alone (Jokiel and Coles, 1990).

### Coral reproduction and dispersal

Reproductive activity (gametogenesis) in some important reef-building coral families (e.g. Pocilloporidae, Poritidae, and Agariciidae) in the Eastern Pacific can either be detrimentally affected or enhanced by ENSO-related seawater warming. Moderate to weak events can improve conditions for reproductive success since reproduction typically occurs under warmer conditions; however, strong events can cause reproductive failure if temperatures rise too high (Colley et al., 2006). Corals disperse to the tropical eastern Pacific via countercurrents that transport water from the west to the east. During ENSO warm phase, the intensity of these currents increase, possibly allowing a more rapid

transport of larvae and improved chances for dispersion and recruitment of corals originating in the Central Pacific to the Eastern Pacific (Glynn and Ault, 2000).

### Secondary biological impacts

Secondary impacts to corals following ENSO include bioerosion, predation, and increased susceptibility to disease. Accelerated rates of bioerosion by echinoids occur after coral skeletons are denuded of live tissue allowing overgrowth by algae. As the echinoids browse, they remove small amounts of carbonate, and when populations are high, entire reef structures can be eliminated. This was observed following the 1982–1983 ENSO, where pocilloporid reefs were reduced to sand and rubble by the echinoids *Eucidaris galapagensis* (in Galapagos) and *Diadema mexicanum* (in Panama) (Glynn, 1988; Eakin, 2001).

Reductions of coral populations directly affect their predators (corallivores), such as the Crown of Thorns starfish (*Acanthaster planci*). When less prey are available, predator populations decrease. Furthermore, focused predation on surviving coral colonies can result in addition loss of coral cover. Since ENSO-related mortality is greater in some coral species than others, prey switching may occur, especially if more desirable species suffer population declines (Glynn, 1990).

### Summary

El Niño, La Niña, and ENSO are related but distinct phenomena that affect corals, particularly in the eastern tropical Pacific. Teleconnections to adjacent regions also affect corals in the Western Caribbean, Central and Western Pacific, and the Indian Ocean. Elevated temperature anomalies result in up to 99% coral mortality in the most strongly affected areas. Other impacts related to ENSO, notably sub-aerial exposure associated with sea level decrease, also negatively affect corals.

## Synonyms

Biorock; Electric artificial reef; Electro mineral accretion of minerals in seawater

## Definition

Electro mineral accretion (EMA) artificial reefs are metal structures used to secure transplants and promote the growth of scleractinian corals (Hilbertz and Goreau, 1996) and to provide a nature-like colonization substrate (Schuhmacher and Schillak, 1994).

EMA artificial reef structures act similar to an electrolytic cell. They consist of a metal frame upon which coral transplants are attached. An anode (made of a slowly oxidizing metal) is placed in the direct vicinity of the frame (cathode), with a weak DC electrical current applied to the set up. Sea water acts as the conductive electrolyte solution between the cathode and the anode. The applied electric current causes the deposition of minerals, such as  $\text{CaCO}_3$ ,  $\text{Mg}(\text{OH})_2$ ,  $\text{CaSO}_4$ , and  $\text{NaCl}$ , on the structure (Meyer and Schuhmacher, 1993; Hilbertz and Goreau, 1996). This is due to a reduction reaction taking place on the negatively charged cathode of the electrolytic cell (EMA artificial reef). The product of the reduction reaction which is of benefit to the corals is  $\text{CaCO}_3$ , as this is the primary compound that forms the skeletons of scleractinian corals.

The EMA process has been found to significantly increase growth rates of scleractinian coral transplants (Sabater and Yap, 2002, 2004; Eggeling, 2006). Increased skeletal growth rates have been attributed to an increase in mineral ion concentration within the vicinity of transplants attached to the cathode causing a diffusional influx of ions into the coral polyp's coelenterons, increasing the availability of ions for calcification (Sabater and Yap, 2004). Corals face a production trade-off between allocating resources into colony growth or production of reproductive cells (Rinkevich, 1996). Debate has developed regarding the use of habitat forming organisms with

artificially altered physiological traits in environmental restoration.

EMA artificial reefs have been installed for diving tourism (Van Treek and Schuhmacher, 1998) in many areas and have suffered from degrading natural coral reefs. They have also been promoted and implemented for coral reef restoration projects. Rapidly growing corals may have significant potential to be used in coral reef restoration projects for stabilizing substrate and promoting growth of key habitat forming species of coral. The technology has also been utilized for rapidly growing corals for use in aquaria (Eggeling, 2006).

## Definition

The electron spin resonance (ESR) dating method is one of several radiation exposure methods based on radiation

dosimetry such as thermoluminescence (TL), optically stimulated luminescence (OSL), and radioluminescence (RL). All these methods use the phenomenon of common minerals acting as natural dosimeters. The radiation (natural radioactivity and cosmic rays) causes charge (electrons, free radicals) which is trapped at defects in the crystal lattice of a wide range of minerals such as aragonite, calcite, and quartz. Here, we will focus on dating aragonite coral samples. The trapped charges from paramagnetic centers can be detected by the rise of a characteristic ESR signal. The amount of trapped charge accumulation (paleodose,  $D_E$ ) increases with time and can be quantified by the ESR measurement. An ESR age is calculated by dividing the accumulated paleodose ( $D_E$ ) by the dose rate of the natural radiation ( $D'$ ) (Figure 1).

## Introduction

The first systematic studies and application of ESR dating of corals were published as early as the late 1980s (e.g., Ikeya and Ohmura, 1983; Radtke and Grün, 1988; Radtke et al., 1988; Grün et al., 1992), and since then several methodological improvements and the development of

more stable and high-resolution ESR spectrometers have significantly increased the quality of ESR dating results. Now, it is not only possible to distinguish between the major periods of high sea level during the last 500,000 years but also to differentiate between sub-maxima, for example, during the marine isotope stage (MIS) 5 sea-level highstand (e.g., Schellmann et al., 2004a; Schellmann and Radtke, 2004a). However, a precondition is that numerous corals from one stratigraphic unit and ideally from several locations are dated. Then, the effect of weak weathering and slight recrystallization from a primary aragonite to a calcite coral fabric and the resulting underestimation of the ESR ages can be detected from the scatter of individual results.

The high accuracy of ESR dating applied to corals is strongly supported by the comparison of ESR dating results with radiocarbon ( $^{14}\text{C}$ ) and thermal ionization mass spectrometry (TIMS)  $^{230}\text{Th}/^{234}\text{U}$  data.

## Methodology

Detailed overviews of the physics and the application of the ESR dating method have been provided, for example,

Electron Spin Resonance Dating (ESR), Figure 1. Generalized principle of ESR dating of aragonitic coral.

by Ikeya (1993), Grün (2007), Rink (1997), and Jonas (1997). Most recently, Schellmann et al. (2008) have reviewed the accuracy of ESR dating of different materials like coral, mollusc shells, and quartz; Blackwell (2006) has focused on ESR dating in Karst environments; and Grün (2006) has given a detailed description of ESR dating of human teeth.

As already stated, the ESR dating method uses the phenomenon that common minerals, like the aragonite fabric of corals, act as natural dosimeters. An ESR age is derived from the ratio of the accumulated radiation dose  $D_E$  (equivalent dose) to the natural radiation rate  $D'$  (dose rate), to which the sample was exposed in the past (Figure 1).  $D_E$  is determined by an additive dose method. For this method, 20 or more aliquots of the same sample are stepwise irradiated with increasing artificial  $\gamma$ -doses (e.g., using a  $^{60}\text{Co}$  gamma source). The growing amplitude of the ESR signal at  $g = 2.0007$  of a coral sample is proportional to the number of trapped charges ( $D_E$ ), which is dependent on the strength of natural irradiation (dose rate,  $D'$ ) and on the radiation time (= age of the sample). A living coral does not contain the ESR dating signal at  $g = 2.0007$ , which means that the ESR intensity is zero.  $D_E$  is determined by extrapolating the resulting dose response curve to zero ESR intensity. In the case of dating corals, the  $D_E$ - $D_{\max}$  plot procedure (D-DP procedure) should be used for the calculation of  $D_E$  as described by Schellmann and Radtke (2001). The former natural dose rate ( $D'$ ) of a coral sample is estimated on the basis of the content of uranium (other radioactive elements like Th and K are of no relevance) and the intensity of the cosmic dose rate. The correct determination of  $D'$  and  $D_E$  is essential for any ESR age estimation.

Improvements in annual dose rate ( $D'$ ) estimation and the newly developed approach of equivalent dose ( $D_E$ ) determination ( $D_E$ - $D_{\max}$  plot procedure) increase the precision of ESR dating of Holocene and Pleistocene corals (Schellmann et al., 2008). This is strongly supported by comparing ESR dating results with other numeric dating methods such as radiocarbon ( $^{14}\text{C}$ ) and TIMS U-series analysis (TIMS  $^{230}\text{Th}/^{234}\text{U}$ ).

### Case study 1: ESR dating of Pleistocene coral reef terraces

Since several early systematic studies have been carried out (e.g., Ikeya and Omuhra, 1983; Radtke and Grün, 1988), dating of corals is one of the most common applications of ESR dating. It has been widely applied for dating sequences of raised coral reef terraces with ages of up to 500–600 ka, e.g., on Sumba island (Pirazzoli et al., 1991); on Huon Peninsula, New Guinea (Grün et al., 1992); on Curaçao, Netherlands Antilles (Radtke et al., 2003; Schellmann et al., 2004b); and on Barbados (e.g., Radtke et al., 1988; Schellmann and Radtke, 2004a, b).

The ESR dating of the fossil coral reef terraces on Barbados provides an impressive example of the application of this method (e.g., Schellmann and Radtke, 2004a, b).

On this Caribbean island, several uplifted Pleistocene coral reef terraces are well preserved, rising up to 122 m above modern sea level in southern Barbados (Figure 2). By using morpho- and chronostratigraphic methods, the area between the present coastline and the center of southern Barbados can be subdivided up to 13 clearly distinguishable main coral reef terraces (T1 to T13) and some less prominent sub-levels (for example T-6a and T-6b, T-1a<sub>1</sub>, and T-1a<sub>2</sub>). The youngest formations are located at the lowest elevations close to the present coast, while older reef terraces have higher elevations and generally a greater distance from the coast. Due to the relatively slow uplift rate in southern Barbados (approx.  $0.27 \pm 0.02$  m/1,000 a), the youngest Pleistocene coral reefs (T-1a<sub>1</sub>) have been formed at approx. 74 ka (ESR) or 77 ka (TIMS Th/U) and the oldest and highest coral reef (T-13) during a sea-level highstand approx. 410 ka (MIS 11). This correlation between age and height of the terraces allows us to calculate neotectonic movements and to estimate paleo sea-level changes (e.g., Schellmann et al., 2004a; Radtke and Schellmann, 2005).

Generally, the timing of coral reef growth calculated by both dating methods agrees well, especially when the error ranges are considered. However, a detailed comparison of dating results of both methods shows that many ESR ages are up to 5–10% younger than the corresponding U-series ages, perhaps the result of a slight overestimation of the alpha-efficiency (0.05) used for ESR age calculations or of weak recrystallization processes that influence the ESR more strongly than the U-series data. The comparison also shows that the apparently minor analytical errors (precision) of U-series data (less than 1%, ESR between 5–8%) give no evidence of a better time resolution (Schellmann et al., 2004a). The latter can be demonstrated well by the relatively high scattering of both ESR and TIMS U-series data inside an individual Late Pleistocene coral reef deposit. For example, comparing the results of ESR and TIMS U-series dating of MIS 5a-1 corals, carried out on paired samples from Inch Marlowe Point location on Barbados (Figure 3), shows that the spread of individual ages (not considering errors) for both methods is about 4,000 years, although all ages were produced on individuals from the same branch of coral which are hence most likely of the same age (grown within not more than a few hundred years). Therefore, age differentiations between single Late Pleistocene coral reef deposits that have developed in time periods of less than 4,000–5,000 years are rarely reliable, independent of the applied dating technique (ESR or TIMS U-series).

### Case study 2: ESR dating of Holocene corals

The accuracy of ESR dating on paired samples of Holocene corals has been tested by Radtke et al. (2003) using 21 radiocarbon-dated Late and Middle Holocene coral samples from Tsunami deposits found on Bonaire and Curaçao (Netherlands Antilles) (Figure 4). The calibrated radiocarbon ages spread between recent and 3,644 years

**Electron Spin Resonance Dating (ESR), Figure 2.** ESR and TAMS U/Th ages of uplifted Pleistocene coral reef terraces from Southern Barbados. Details are provided in Schellmann and Radtke (2004a, 2004b).

**Electron Spin Resonance Dating (ESR), Figure 3.** ESR and TAMS U/Th ages ( $\delta^{234}\text{U} > 141$  and  $< 157\text{‰}$ ) of MIS 5a-1 coral reef terrace near Inch Marlowe Point, southern coast of Barbados (slightly modified after Schellmann et al., 2004a).

and the ESR ages were between 9 and 3,653 years (not considering the individual uncertainties of each measurement). Except for one sample (outlier), the ages determined by both methods are consistent within an error range of approx. 250 years. Considering the small amplitude of the ESR dating signal from such young coral samples, the good agreement between radiocarbon and ESR data is astonishing. Nevertheless, U-series dating of

Holocene corals is much more precise than both ESR and radiocarbon dating.

### Summary

Due to methodological advances, which significantly increase the accuracy of ESR dating of Pleistocene and Holocene corals, ESR dating has become an efficient tool in earth sciences for geochronological studies on coral reef

**Electron Spin Resonance Dating (ESR), Figure 4.** Comparison of ESR and radiocarbon ages of Holocene corals from Aruba, Bonaire and Curacao (Netherlands Antilles). Calibrated radiocarbon ages were corrected for marine reservoir effect (slightly modified after Radtke et al., 2003).

terraces in the past decade. ESR dating of Holocene corals coincides with the variability of  $^{14}\text{C}$  ages caused by the marine reservoir effect, but without any doubt TIMS U-series dating of Holocene coral is more precise, much faster, and much cheaper than ESR dating. ESR dating of Pleistocene corals permits us to differentiate between the main marine isotope stages (MIS) 5, 7, 9, 11, and 13 as well as between the substages 5e-2,3 and 5e-1, 5c, and 5a-2 and 5a-1. The average error is about 5–8%. Late Pleistocene corals can be dated with a similar accuracy as with the TIMS U-series method in this time range, although the individual errors of ages are significantly larger than those of U-series data. The advantage of ESR, however, is that the upper dating limit for corals is probably above 500,000 years. If weathering and recrystallization from primary aragonite to calcite of the coral material could be excluded, dating of coral with an age of several million years should be feasible from the physical point of view. All in all, future research in ESR dating corals should be focused on (a) a more precise identification of diagenetic transformations of the primary aragonitic fabric of the coral samples and (b) on the creation of a single-aliquot dating technique that uses orientated aragonitic polycrystals.

### Synonyms

Coral terraces; Raised reefs; Reef terraces

### Definition

Emerged reefs are dead reefs (Figure 1), which emerge generally after the fall of the “relative” sea level due to various factors or triggers (1) uplifts in areas that are tectonically active; (2) the loading of the oceanic basins following the last deglacial sea-level rise (hydroisostatic readjustment); (3) decrease of the sea level resulting from glacioeustatic variations; and (4) lithospheric flexure. Consequently, the emerged reefs can be expressed by more or less narrow reef “flats” immediately at the rear of modern coral reefs, series of uplifted coral terraces, partly emerged coral buildups, and microatolls (see chapter *Microatoll*).

### Introduction

Emerged reefs are former living coral reefs, which are now subaerially exposed for several reasons. Emerged reefs have been observed in both the Caribbean and the Indo-Pacific. The presence of such emerged reefs was reported in the early works on coral reefs in various parts of the world. In 1842, Darwin reported the presence of raised coral reefs for example in Mauritius and in the Red Sea. He noted in 1842 that the “upraised coral islands in the Pacific” had not been examined by geologists. In 1872, Dana interpreted the presence of elevated reefs in the Pacific as resulting from uplift. Since these older works, several reasons have been invoked to explain the exposure

of these unique morphological features. Extensive series of emerged reefs can be observed in the tectonically active regions. One of the best studied series of coral terraces is located on the Huon Peninsula in Papua New Guinea (Chappell, 1974). This site provided vital information on the tectonic context and calculation of eustatic sea-level variations, made from the dating of corals from these terraces (Bloom et al., 1974; Chappell et al., 1996; Cutler et al., 2003). Other areas of tectonic uplift and reef terraces have also been studied as for example:

- In the Caribbean (Mesolella, 1967; Matthews, 1973; Bender et al., 1979; Blanchon and Eisenhauer, 2001; Feuillet et al., 2004), especially the well-known terraces from Barbados
- Vanuatu (Mitchell, 1968; Neef and Veeh, 1977; Taylor et al., 1980)
- Solomon islands (Mann et al., 1998; Taylor et al., 2005)
- Fiji (Nunn et al., 2002)
- Ryukyus (Konishi et al., 1974; Nakamori et al., 1995; Sagawa et al., 2001; Sasaki et al., 2004)
- Indonesia (Pirazzoli et al., 1991; Hantoro et al., 1994; Bard et al., 1995)
- Red Sea (Gvirtzman et al., 1992; El Moursi et al., 1994; Gvirtzman, 1994)

Lithospheric flexures are also one of the main causes invoked to explain the presence of raised atolls in certain parts of the Pacific as observed in the Cook-Austral islands (McNutt and Menard, 1978) or in New Caledonia (Dubois et al., 1974, 1988). Some recent emergence of corals and coral reefs can be attributed to isostatic readjustments as reviewed and analyzed in some Pacific islands by Grossman et al. (1998) and Dickinson (2001, 2004). Analyses of coral growth of microatolls also document minor vertical displacements (see Chapter *Microatoll*). In this chapter, the various types of “emerged reef” features will be reviewed and the main causes invoking the emersion of reefs and/or corals examined.

### Types of emerged morphological structures

The emerged reefs can be illustrated by several morphological features from series of coral terraces (Figure 2a and b) to slightly emerged reefs (Figure 3) to fields of single coral microatolls. However, emerged microatolls do not always relate to the type of emergence shown by other factors such as the removal of shingle ridges during storms which may result in a fall in low-tide water levels and leave former microatolls stranded.

The major types of emerged reef structures are as follows.

#### Abraded reef flats

Emerged reefs can be found immediately behind the modern coral reef flats and very close to the modern sea surface (Figure 2b). Following an emersion (e.g., caused by a single tectonic event), the coral reef exposed to the waves, storms, and swell is rapidly abraded in a few years.

**Emerged Reefs, Figure 1** Emerged reefs in Vanuatu (photo G. Cabioch/IRD).

**Emerged Reefs, Figure 2** Various types of emerged reef features. (a) Coral terraces; (b) abraded reefs.

**Emerged Reefs, Figure 3** Remnants of slightly emerged reefs in Vanuatu (photo G. Cabioch/IRD).

Some of these abraded reef flats can be observed in the islands of insular arcs as for example in Vanuatu (Taylor et al., 1987).

### Coral terraces

Emerged coral reefs forming a series of terraces result over long periods of time from both glacioeustatic sea-level variation and from tectonic uplift (Figure 2a). These often

contain marine notches and are generally characterized by typical reef morphological features including reef crest, lagoon, etc. The most studied sequences are on Barbados (Mesoletta, 1967; Broecker et al., 1968) and on the Huon Peninsula in Papua New Guinea (Bloom et al., 1974; Chappell, 1974).

### Uplift in island arc archipelagos and tectonically active areas

The island arc archipelagos in tropical areas reveal the presence of elevated coral terraces. Coral dating coupled with morphological and paleoecological studies give information on both vertical motions and past sea-level variations over the Late Quaternary. Reconstruction of past sea levels can be made from calculations using the radiometric age of the emerged reef terraces and known rates of uplift [e.g., from the present elevation of the last interglacial (Stage MIS5e)]. Where rates of uplift are particularly high and relatively steady, terraces, which were originally below modern sea level (e.g., last glacial stadials and interstadials), have now emerged and allow the accurate calculation of these low sea levels.

Locations with intensive studies include Papua New Guinea (Bloom et al., 1974; Chappell, 1974; Chappell et al., 1996), Barbados (Broecker et al., 1968; Bender et al., 1979), Indonesia (Pirazzoli et al., 1991; Bard et al., 1995), Vanuatu (Neef and Veeh, 1977; Mitchell, 1968;

Jouannic et al., 1980; Taylor et al., 1980, 1987), and the Ryukyus (Konishi et al., 1974; Nakamori et al., 1995).

### Caribbean: Barbados

In the tectonically active region of the Caribbea (see *Barbados*), the Barbados emerged reefs are probably one of the most studied sequences of raised coral terraces and are, with the Huon Peninsula, one of the most important data set in the world on the knowledge of the Late Quaternary sea-level variations. Previous works by Mesolella (1967) showed the presence of up to 18 morphological emerged reef features and provided data on the ecology and the development of these formations. The lower terraces were dated by Uranium series dating giving ages of 122, 103, and 82 ka (1 ka = 1,000 years) (Broecker et al., 1968). These ages were found in the coral terraces and were labeled as Barbados I (+6 to +20 m depending on the sites and the uplift rate), Barbados II (+21 to +27 m), and Barbados III (+24 to +55 m), respectively. Taking into account the local uplift rate, Broecker et al. (1968) reconstructed the past sea-level variations of these periods. They obtained a 122-ka (corresponding to the Marine Isotope Stage 5e, MIS 5e) high stand at +6 m above the modern sea level and 103-ka (MIS 5c) and 82-ka (MIS 5a) high stands at -13 m below the modern sea level. These results were of broad importance, since they were (and still are) used as a world reference. Similar works were performed in several other sites on Barbados by Bender et al. (1979). Further studies on Barbados provided new data on the timing and the magnitude of these high stands (Schnellmann et al., 2004). Recently, a detailed survey on the distribution of reef facies performed in the west and south of Barbados provided a revised model of reef history during the last interglacial period (MIS 5) including three stages of development in relation to the sea-level variations (Blanchon and Eisenhauer, 2001).

### Pacific: Papua New Guinea

Chappell (1974) described in Papua New Guinea (PNG) (see *Huon Peninsula, P.N.G.*) a series of coral terraces on the Huon Peninsula, close to the New Britain trench at the boundary between the Australian and the Pacific tectonic plates. These terraces are characterized by a decrease of the uplift rate from south to north. They were first linked with sea-level variations by Fairbridge (1960, in Chappell, 1974). These terraces are represented by more than 20 elevated coral reefs, some of them revealing fossil reef crests and lagoons, and are particularly well developed along 80 km. They were dated by Veeh and Chappell (1970) at 30, 40, 50, 60, 80, 105, 120, 140, 185, and 220 ka, the higher by Uranium series dating. These authors underlined that the succession of such sea levels supports the Milankovitch astronomical theory, indeed, recording both eustatic sea-level variations and vertical motions (Chappell, 1974). In 1974, Bloom et al. reported new Uranium dates and proposed an improved sea-level variation curve for the last 125 ka (Figure 4). Among the flight of coral terraces, they identified the main "reef complexes" I, IIb, IV, V, VI, and VII dated at 5–9 ka, 41 ka, 61 ka, 85 ka, 107 ka, and 118–142 ka, respectively. Estimation of uplift rates was from the analyses of six cross sections and by comparison with the Barbados sea-level estimates. They proposed paleo-sea levels of +6 m, -15 m, and -13 m for the highstands of 125 ka, 103 ka, and 82 ka, respectively. The 60-ka, 42-ka, and 28-ka sea levels were estimated at -28 m, -38 m, and -41 m, respectively. Although numerous data were obtained in Papua New Guinea and in other sites including Barbados, some discrepancies appear between the sea-level record reconstructed from isotopic data (Marine Isotopic Stage, MIS) and coral dating (Chappell and Shackleton, 1986), especially the period ranging from 30 to 70 ka (=MIS 3). Chappell et al. (1996) "revisited" the sea-level estimates from PNG coral terraces taking into account new dates in the range of 30–62 ka and bathymetric range

**Emerg ed Reefs, Figure 4** Sea-level curve of the last 125 ka proposed by Bloom et al. (1974) (modified after Bloom et al., 1974).

of these dated corals. From these new results, there is a better constraint of the sea-level estimates between the isotopic data and the coral dating. New dates were obtained from the Huon Peninsula in 2003 by Cutler et al., using high-precision  $^{231}\text{Pa}$  and  $^{230}\text{Th}$  dating methods. They were focused on the Marine Isotope Stages 5 and 3. These authors provided data regarding the timing and the magnitude of the relative high stands and their transition during the MIS 5 sea-level variations. Moreover, some inputs were made on the relative sea-level variations of the MIS 3, with sea-level estimates ranging from 60.6 to 36.8 ka from between  $-85$  and  $-74$  m. In addition, all these studies on coral reefs from PNG provided information on deep ocean temperatures (Chappell and Shackleton, 1986; Chappell et al., 1996) highlighting the differences in the deep ocean temperature change from MIS 5 (125 ka) and MIS 2 (24 ka) and between Atlantic and Pacific Oceans (Cutler et al., 2003).

#### Pacific: Vanuatu

Vanuatu (see *Vanuatu*) is an island archipelago located in the South-West Pacific at the convergent boundary of the Australian, Pacific, and North Fiji Basin tectonic plates. Early works performed by Mitchell (1968) in Malakula, Neef and Veeh (1977) in Efáté, and Jouannic et al. (1980) and Taylor et al. (1980) in Espiritu Santo and Malakula revealed the presence of several elevated coral reefs. Even earlier, Stearns (1945) was one of the first scientists to try to interpret the presence of Pleistocene raised coral reefs in Espiritu Santo. In Efáté (or Vaté), Neef and Veeh (1977) identified sea levels of the last 125 ka by dating these emerged coral reefs. In the North of Malakula, previous works identified six main terraces culminating at about 350 m but some discrepancies in altitude occur, probably due to coral reworking and/or errors in altitude assignment (Mitchell, 1968; Jouannic et al., 1980). A survey performed in 2001 by Cabioch and Ayliffe provided more recent U/Th coral dating of these raised terraces and also observed several minor terraces. An estimate of the sea-level highstands from MIS 3 (55–40 ka) was given. These sea-level estimates are in good agreement with the data from PNG (Chappell et al., 1996). The North of the island of Malakula and the south and the east of the island of Espiritu Santo are also characterized by a series of raised terraces which were dated by Jouannic et al. (1980) and Taylor et al. (1980, 1987, 1990), providing information on vertical motions in relation to the D'Entrecasteaux Ridge collision (see Chapter *Vanuatu*). Moreover, in this area, Taylor et al. (2005) showed the occurrence of a Late Quaternary cycle of uplift and subsidence in Espiritu Santo over one or two hundred thousand years, interpreted as resulting from subduction of morphological features at the D'Entrecasteaux Zone.

#### Pacific: Solomon islands

South of Papua New Guinea and north of Vanuatu, the Solomon Islands, at the boundary convergence of the

Australian and Pacific tectonic plates, are also characterized by raised reefs. In comparison with studies performed in PNG and Vanuatu, very little is known about these raised terraces. Stearns (1945) indicated the presence of raised reefs in Guadalcanal, then in 1969, Stoddart extensively described the geomorphology of the Solomon Islands including elevated fringing and barrier reefs. Similarly to the Vanuatu archipelago, coral dating by Taylor et al. (2005) revealed the occurrence of a Late Quaternary cycle of uplift and subsidence in the central part of the New Georgia Island Group interpreted as resulting from subduction of the Coleman seamount or other prominent morphological features.

#### Pacific: Fiji

The islands of Fiji are located on the northern end of the Lau ridge, an old island arc. Elevated reefs were dated to the MIS 5 (125-ka highstand) (Nunn et al., 2002). Two alternative explanations were given by these authors to explain the elevation of these reefs. The Vanuabalavu island group could have been affected by the loading on the lithosphere inducing subsidence and reef uplift or alternatively it could be from the continuing anticlockwise rotation of the Fiji platform.

#### Pacific: Ryukyu

In the North-West Pacific, in the tectonically active region of the island arc at the boundary between the Amami Plateau in the Philippine Sea and the Eurasian tectonic plates, the Ryukyu Islands (see *Ryukyu Islands*) display sequences of emerged coral reefs. Kikai-Jima displays the highest uplift rate. These elevated reefs were described by several previous authors, and among these, Konishi (1974) provided Uranium and C14 dating of the five well-preserved coral terraces covering the period of the last interglacial period (the last 125 ka). Sugihara et al. (2003) focused their studies on the four Holocene raised coral reef terraces reaching an altitude up to 10 m and showed that these four terraces resulted from successive seismic uplifts. Sasaki et al. (2004), in the north of Kikai island, dated the coral terraces reaching an altitude from 15 to 65 m. The Uranium ages showed the occurrence of several reef sequences ranging from 75 to 51 ka. In addition to these works, older Pleistocene reef formations (400–500 ka) were described in the Ryukyus by Nakamori et al. (1995) based on geochronological dating and calcareous nannofossil biostratigraphy.

#### Indian Ocean: Indonesia

In Indonesia (see *Indonesian Reefs*), at the boundary of several tectonic plates, many islands display sequences of raised coral terraces. Chappell and Veeh (1978) in Atauro Island and in Timor reported some raised reefs reaching an altitude up to 600 m. In Atauro, the lowest terraces reaching a maximum of 65 m were dated as last interglacial (the last 125 ka). Later, additional sequences of raised reefs were described in the region of Sumba

Island (Pirazzoli et al., 1991; Bard et al., 1995) and again on Alor Island (Hantoro et al., 1994). In Cape Laundi (Sumba), Pirazzoli et al. (1991) described the occurrence of six reef complexes labeled I–VI, reaching an altitude of 475 m and dated by Electron Spin Resonance and Uranium series methods at 1 million years. The accurate dating of corals from the reef complexes I and II revealed a polycyclic origin for these terraces with ages from the MIS 5 (86, 105, 125 ka in the complex I and 130 ka in the complex II) and MIS 9 (280 and 355 ka in the complex II). The sequence of raised reefs on Alor Island described by Hantoro et al. (1994) is composed of six main coral terraces reaching an altitude of 700 m. Uranium series dating methods provided data to identify the terraces from the Holocene, MIS 5c, 5e, and 7. Based on the uplift rate of the dated terraces, an age was calculated for the highest terraces.

### Red Sea

The Red Sea (see *Red Sea and Gulf of Aqaba*) region is tectonically active as the Red Sea has been opened by sea-floor spreading. In this region, a series of raised terraces was reported by various authors. In the southern Sinai, Gvirtzman et al. (1992) reported the occurrence of several emerged reefs distributed into several morphological complexes. Gvirtzman (1994) performed a morphological description of these features and provided U/Th dating records for some of these terraces. Using these dates and taking into account the uplift rate, he estimated the age of other terraces which were not dated. As a result, ten low and high sea-level stands were identified from today to 330 ka. In another site in the Red Sea, in the coastal plain of Egypt, El Moursi et al. (1994) surveyed a sequence of eight emerged coral terraces including morphological description and Uranium series dating. The highest terraces labeled 8 reach an altitude ranging from 9 to 35 m, the intermediary terraces 5–7 from 22 to 32 m, and the lowest terraces 1–4 from 2 to 9 m. Because the coral from the highest terraces were recrystallized, only the lowest terraces 1–3 were dated from 72 to 131 ka with a large range of intermediary dates. These dates clearly indicate that these coral reefs were formed during the last interglacial period (125 ka, MIS 5). Based on the chronostratigraphy of the sea-level variations, these authors advanced the hypothesis that the terraces 5–7 were formed during the MIS 7 (230 ka) and the terrace 8 during the MIS 9 (330 ka).

### Lithospheric flexure

Emerged uplifted coral terraces and atolls can provide proof of the occurrence of lithospheric flexures due to a bulge at the rear of trenches or due to the loading of active volcanos in hotspot areas (e.g., Lambeck, 1981). In the central Pacific, McNutt and Menard (1978) observed the presence of raised atolls in the Cook and Society archipelagos in the vicinity of still or recently active volcanoes resulting from deformation caused by

volcanic loading. They performed a model taking into account the elevation of these raised atolls which can give reliable data for the lithospheric flexure. Pirazzoli and Montaggioni (1998) dated some of the raised corals which were interpreted as resulting from this lithospheric flexure. The elevation of coral reefs in the vicinity of New Caledonia in the South-West Pacific provides another example of lithospheric deformation (Figure 5). The islands of the Loyalty ridge, from the south to the north, Maré, Lifou, and Ouvéa are uplifted close to the Vanuatu trench where the Australian plate dips beneath the Pacific plate and the North Fiji basin microplate. Only the eastern part of Ouvéa is uplifted, while the western part is still submerged. The uplift of the Loyalty Islands and the differences of elevation observed at Ouvéa illustrate particularly well the lithospheric deformation of the bulge formed just at the rear of the subduction zone (Dubois et al., 1974, 1988) as also confirmed by the magnetostratigraphy performed on Maré Island (Guyomard et al., 1996). Another example of lithospheric flexure marked by raised corals can be found in the Hawaii hotspot area (Grigg and Jones, 1997). Although the numerical models agree with the observations, these authors did not exclude the coexisting presence of tsunami deposits at this site.

### Isostatic readjustment

On numerous Indo-Pacific islands and reefs, less prominent emerged features have been described including abraded reef flats, emerged cemented deposits (beneath which in situ coral heads may occur), and microatolls growing at heights above that at which they grow today (e.g., Dickinson, 2004). A mid to late Holocene age has been established for these features, which generally show an emergence of between 1 and 3 m. The occurrence of this level and its altitude in 92 records from the Pacific were reviewed by Grossman et al. (1998). These islands far from the polar regions have been submitted to isostatic and gravitational readjustments resulting from the melt-water load on the oceanic floors and depending on the underlying mantle viscosity (Nakada, 1986; Nakada and Lambeck, 1989). Grossman et al. (1998) noted that the geophysical model of the rheological response to the last deglacial melting of the continental ice is in good agreement with the field data, i.e., 1–3 m higher than that present between 5 and 1.5 ka, (for example see Nakada and Lambeck, 1989; Lambeck and Nakada, 1990 for an Australian example). Variations occur even across continental shelves and between island groups and there is an absence of these features in the Caribbean where postglacial hydroisostatic emergence did not take place.

### Magma chamber inflation

In the volcanic island of Tanna (Vanuatu), some corals uplifted between 155 and 15 m were dated by Chen et al. (1995) of A.D. 1002 and A.D. 1878, respectively. The occurrence of such emerged corals at such an elevation was interpreted by the authors as resulting from the

**Emerged Reefs, Figure 5** Elevation on the lithospheric bulge of the uplifted reefs and atolls of the Loyauté Ridge (modified and simplified after Dubois et al., 1988).

magma chamber inflation of the active volcano Yasur. Moreover, they estimated the recurrence interval from 125 to 250 years.

### Summary

The emerged reefs can be expressed by several morphological features from the single coral colony (microatoll) to extensive development of coral terraces. Several causes can be invoked to explain the occurrence of emerged reefs in the various regions of the world. Among these causes, the uplift of coral reefs in tectonically active regions is probably the most widespread. Nevertheless, the occurrence of such coral terraces in these tectonic zones is also dependant on eustatic sea-level variations. Several sites in the world display extensive sequences of raised reefs including the well-known sites from Barbados in the Caribbean, Papua New Guinea and Vanuatu in the Pacific Ocean, and Indonesia in the Indian Ocean. Uplifted atolls in some parts of the world can also attest to the presence of lithospheric flexures as observed in the Cook-Society Islands or in the Loyalty Islands. Isostatic readjustments can be invoked to explain the mid-Holocene relative high sea level. The research carried out on these morphological features has highly improved

our knowledge of Late Quaternary climatic and eustatic sea-level variations, their tectonic context, and also the upper earth rheology. Further studies will provide additional data on these topics of broad interest in the framework of earth science.

## ENEWETAK ATOLL, MARSHALL ISLANDS

James E. Maragos

U.S. Fish and Wildlife Service, Honolulu, HI, USA

## Introduction

The Marshall Islands consist of 29 atolls and 5 isolated reef islands in the northwest central Pacific Ocean. The archipelago contains the largest and perhaps oldest atolls in the world based on the findings of deep drilling surveys at Enewetak (formerly called Eniwetok) and Bikini (Figure 1) and the archipelago's location near the oldest part of the Pacific Plate. Enewetak Atoll ( $11^{\circ}30'\text{N}$ ,  $162^{\circ}15'\text{E}$ ) (Figure 2) is located in the northwest corner of the Republic of the Marshall Islands, and is the second largest atoll in the Marshall Islands in terms of combined lagoon, reef, and land area ( $1,027\text{ km}^2$ ). Enewetak Atoll and neighboring Bikini Atoll collectively served as the major American proving ground for nuclear weapons testing after World War II that led to the most comprehensive scientific and engineering studies of deep ocean atolls in the world. Enewetak is part of the arid northern Marshall Islands where vegetation, groundwater, and rainfall ( $1,470\text{ mm/year}$ ) are less compared to those characterizing the central and southern Marshall Islands. However, rainfall can be highly variable ranging from 605 to  $2,422\text{ mm}$  per year. Surface ocean water temperatures normally range from  $25^{\circ}\text{C}$  to  $29^{\circ}\text{C}$  per year. The collective land area of the atoll is  $5.8\text{ km}^2$  with many larger islets concentrated on the eastern half and only smaller ones on the southwest quadrant of the atoll. The atoll supported 41 low coral islets mostly along the perimeter reef, until one on the northern rim (Elugelap) was first drilled and then completely destroyed and the other two (Sanil and Teiter) partially destroyed during the “Mike” hydrogen bomb test of 1952.

## Physical characteristics

The Enewetak perimeter reef shows a circumference of 122 km, and three large passes cut through the perimeter reef connecting the ocean to the lagoon. These occur along the southeast (1.5 km wide, 55 m depth), south (9.5 km wide, 10–20 m deep), and southwest (6 km wide, 2–4 m deep) parts of the perimeter reef. All show strong reversing currents during ebb and flood tides. The prevailing northeast trade winds generate wind waves that break on windward reefs and, via wave set-up, continually drive water across the perimeter reefs and into the northeastern lagoon regardless of the state of the tide. These cooler waters then sink toward the bottom of the lagoon, and warmer excess waters are eventually discharged through the three passes and over leeward SW reef crests. The large lagoon can be subdivided into four sectors depending on the degree of trade-wind fetch: the leeward lagoon in the northeast quadrant, the windward lagoon in the southwest quadrant, and the two transitional lagoon areas at the northwest and southeast quadrants.

**Enewetak Atoll, Marshall Islands, Figure 1** Comparative analysis of drill cores collected at Bikini and Enewetak Atolls, Marshall Islands (Schlanger, 1963 in Ristvet, 1987).

The windward perimeter reef shows distinct ecological and geological zones both at Enewetak and most of the remaining Marshall Islands (see “*Bikini Atoll, Marshall Islands*”). From offshore toward the lagoon, these zones include the following:

- Deep fore reef
- Fore reef terrace
- Spurs and grooves
- Coralline algal reef flat and ridge
- Room and pillar caverns (galleries)

- Micro-atolls (*Porites*, *Heliopora*)
- Moated reef flat
- Lagoon back reef and
- Lagoon floor

The windward reef flat also shows evidence of a higher (>1 m) sea-level stand between 2,200 and 4,000 years ago. The zonation along leeward (southwestern) perimeter reefs shows variable features including

- Shallow passes
- Sand flats

Enewetak Atoll, Marshall Islands, Figure 2 Map of Enewetak Atoll with the Marshallese names of the islands (Reese, 1987).

- Pinnacles
- Coralline algae reef flat with emergent corals (*Acropora*, *Pocillopora*)
- Massive buttresses
- Canyons
- Amphitheatres and
- Steep leeward fore reef slopes

Approximately 158 patch reefs reach the sea surface in the lagoon, and an estimated 3,000 pinnacle reefs, each with at least 4 m of vertical relief, are in the subsurface lagoon that has a maximum depth of 65 m.

### Cultural history

Based upon Marshallese oral tradition, archaeology, and linguistics, the Marshall Islands (including [Enewetak Atoll, Marshall Islands](#)) may have been inhabited for as long as 2,000–3,000 years with the initial explorers beginning their migrations from the Philippine region of South-east Asia approximately 5,000 years ago. The Marshallese

are bonded by a singular culture and language, and the archipelago is divided into two northwest-to-southeast trending geological and cultural chains termed the Ralik (“sunrise”) and Ratak (“sunset”), each with separate leadership hierarchies and cultural lineages. All of the remaining islands and atolls in the archipelago are inhabited except for six arid northern atolls (Ailinginae, Bokaak, Bikar, Taka, Erikub, and Rongerik), one small southern atoll (Ngarikrik), and one central isolated reef island (Jemo). These eight likely served as pantry reserves for neighboring inhabited atolls. The remaining atolls and reef islands were all likely continuously settled except during temporary evacuations from natural disasters. However, from 1946 to 1954 the peoples of Utirik, Rongelap, Enewetak, and Bikini were forced to evacuate their home atolls during the U.S. nuclear testing program, and all have been, or are being resettled, except for Bikini (see “[Bikini Atoll, Marshall Islands](#)”).

The people of Enewetak are the original and only inhabitants of Enewetak Atoll, according to their oral

tradition that also maintains they have lived at their home atoll since the “beginning of time.” The two largest islands, Enewetak in the SE and Engebi in the NE, have served as the two main villages at the atoll. Because of their geographically isolated locale, the Enewetak people and culture as a whole have evolved separately in some respects from their neighbors at the remaining Marshall Islands. Before the previous century, the Enewetak people were known for their long distance travel and navigation, visiting the inhabited islands of the Caroline archipelago to the southeast. They were also known as builders of the largest ocean-going canoes (15 m in length) constructed in the Marshalls at that time.

### Recent history

The Spanish explorer Alvaro de Saavedra is credited for the European discovery of Enewetak Atoll in 1529. Afterward, Enewetak was visited only once in 1792 before Captain Fearn of the vessel *Hunter* mapped the atoll in 1794. In 1898, Germany declared the Marshalls and several other Pacific areas as Protectorates, and a German trader contracted the Enewetak people to extend their plantings to promote the copra trade at Enewetak Atoll and another atoll, Ujelang. Before this time, the Enewetak people never relied much on Ujelang, a much smaller atoll 200 km to the southwest. Ujelang was previously inhabited by a separate clan of Marshallese until most were wiped out by a typhoon near the end of the nineteenth century, with the survivors later migrating to the southern Marshall Islands and never returning.

Japan took possession of most German territories in 1914 when World War I began, including the Marshall Islands and retained custody of them after the war and defeat of Germany via a Mandate from the League of Nations. For 30 years, Japan administered Enewetak from its headquarters at Pohnpei Island in the Caroline Islands because of its closer proximity vis-à-vis the Jaluit Atoll headquarters in the southern Marshalls. In turn, this further isolated the Enewetak people from the remaining Marshallese during the next 3 decades. Japanese rule initially focused on trade, but after 1935, and in violation of the Mandate, Japan began construction of military bases and airstrips throughout the Marshalls, including at Engebi and Enewetak Islands on Enewetak Atoll. The Enewetak islanders were caught in the crossfire during the January 1944 battle of Enewetak between Japanese and American forces. A tenth of the islanders were killed, and virtually all their food crops, vegetation, and dwellings at Enewetak and Engebi Islands were destroyed by the heavy initial bombardment. After the battle, the Americans moved the Enewetak survivors to two small eastern islets at the atoll. By early 1946, the Americans had built a military base at Enewetak and convinced the 141 islanders to temporarily resettle at Ujelang Atoll in order to make way for the nuclear testing program. The islanders did not return to their home atoll for 34 years,

after numerous false promises and 43 nuclear tests from 1948 to 1958 (Table 1, Figure 3) at Enewetak.

### The Nuclear Era

The Americans soon included both Bikini and Enewetak as part of a new U.S. Pacific Proving Ground. The Enewetak islanders remained at Ujelang despite dwindling subsistence resources, expanding population, substandard living conditions, and infrequent visits by supply vessels at the much smaller atoll. Meanwhile at Enewetak, the force of some of the nuclear tests was underestimated, others malfunctioned, and some islands became heavily contaminated with radionuclides, and remained unsafe for resettlement and agricultural use unless cleaned up. In particular, the “Mike” test of 1952 was the first atmospheric detonation of a hydrogen bomb, and created a large crater nearly 2 km across, resulting in the fracturing and slumping of a portion of the northern fore reef just north of the crater (Figure 4).

Finally in 1972, after the threat of protest and legal action, the United States agreed to resettlement after “unspecified activities” were completed. These activities were later determined to be the Pacific Area Cratering Experiments (PACE) designed to evaluate the geological characteristics of cratering from some past nuclear tests by examining existing bomb craters and also simulating their effects by detonating large quantities of conventional explosives at targeted reefs. The PACE program refrained from using radio-nuclides to insure compliance with the provisions of the Partial Test Ban Treaty ratified in 1963. After learning about the potential physical damage from the PACE proposal at a community meeting, the Enewetak people labeled PACE as “evil” and directed their attorneys to sue in U.S. Federal Court, demanding that the proposal be subject to the U.S. Environmental Policy Act. Subsequently, the United States dropped the PACE project, and in 1976 agreed to finance a partial resettlement.

Of particular concern was the incomplete combustion of one test conducted at Runit Island leading to the scattering of plutonium 239 over the island and reef. Given the half life of the isotope is now estimated at 24,000 years (Argonne National Laboratory, 2005), this posed a serious threat to the returning islanders. The United States budgeted \$120 million to collect and place contaminated soil mixed with concrete into Cactus Crater north of the island, and cap it with an 18-in. thick concrete dome (Figure 5a and b). Nevertheless, there was more contaminated soil at Runit than could be encrypted, and a further decision was made to ban the island from all visitation and use indefinitely. After the United States completed other cleanup actions, the remaining 543 Enewetak people were finally repatriated to their home atoll in 1980. Since then the population has fluctuated between 800 and 1,000 residents. In 2000, the Marshall Islands Nuclear Claims Tribunal awarded more than \$340 million to the Enewetak people for loss of use, hardship, medical difficulties, and further nuclear cleanup.

Asterisk (\*) = Elugelap Island destroyed and site became Mike Crater after 10-31-52.

### Enewetak Marine Biological Laboratory

After the initial operations crossroads nuclear tests at Bikini Atoll were completed in 1946, considerable civilian-based research on the geology, oceanography, and ecology of atoll ecosystems was encouraged alongside military-applied research focusing on the impact of the nuclear weapons and movement of radioactivity within

food webs of the atoll and marine ecosystems. Much of this was funded by the Office of Naval Research and the fledgling Atomic Energy Commission (AEC). A Pacific Science Board of the National Academies of Science was established, and many top scientists and engineers were engaged in research including those at the U.S. Geological Survey, Lawrence Livermore National Laboratory,

**Enewetak Atoll, Marshall Islands, Figure 3** Islands of Enewetak Atoll with Marshallese names shown on the lagoon side and the English U.S. government code names on the ocean side (Helfrich and Ray, 1987).

Brookhaven National Laboratory, and dozens of other leading research institutions. A periodical "Atoll Research Bulletin" was initiated in 1950 for publishing new scientific findings on atolls, and the *U.S. Geological*

*Professional Paper* series was expanded to accommodate the results of extensive geological research.

In 1954, Dixie Lee Ray, Director of the Atomic Energy Commission, provided funding for a marine biological

**Enewetak Atoll, Marshall Islands, Figure 4** An aerial view of the large Mike and adjoining Koa bomb craters at the northern rim of Enewetak Atoll in 1978. Note the indentation in the northern ocean-facing reef showing where the Mike hydrogen bomb test caused the spalling and collapse of a sliver of the reef. (Photo courtesy by EG&G Electronics in Tipton and Meibaum, 1981).

laboratory to be established at Enewetak to promote the opportunity for other scientists to visit and engage in field research at the atoll. The Enewetak Marine Biological Laboratory was established in 1955 and directed by marine scientists at the University of Hawaii. Still later the laboratory was reorganized and renamed the Mid-Pacific Marine Laboratory in 1975 to add neighboring Bikini Atoll to the research focus. In 1979, with the cleanup of Enewetak nearing completion, the laboratory was renamed the Mid-Pacific Research Laboratory and down-phased to concentrate on synthesizing the research of the previous quarter century and promoting terrestrial research.

With the resettlement of the Enewetak people completed in 1980 and the subsequent reduction in AEC budgets, the laboratory was closed in 1985 with its biological collections packed and transferred to the Bernice P. Bishop Museum and the Smithsonian's National Museum of Natural History. The reference library of the lab was transferred to the Hawaii Institute of Marine Biology of the University of Hawaii in Kāne'ohe Bay. Over the 30-year period of the lab, 250 formal publications were produced, more than a thousand contributions accessioned, and 1,028 scientists utilized the laboratory. A two volume synthesis of marine research at the lab, *The Natural History of Enewetak Atoll*, was prepared by three dozen scientists and published by the U.S. Department of Energy in 1987.

### Deep Drilling Program at Enewetak Atoll

The earliest modern drilling to learn of the origin of atolls began at Funafuti when British scientists in 1896

penetrated 114 ft. Additional efforts by Japanese scientists led to the drilling at North Borodino to a depth of 1,416 ft. American scientists drilled six holes at Bikini in 1947, two of which penetrated to 1,346 and 2,556 ft. Although all cores had provided evidence of carbonate deposits forming in shallow waters, including corals that had grown in place, none penetrated far enough to reach volcanic base of the atolls. However, in 1951, one Enewetak drill hole at Medren Island off the southern rim penetrated to 4,222 ft (1,267 m) and another Enewetak drill hole at Elugelab Island along the north rim reached to 4,610 ft (1,405 m), with both hitting volcanic bedrock of the upper slope of an extinct volcano rising 5,000 m above the surrounding deep ocean floor, and serving as the base of the atoll. The reef cap above the volcano was estimated at 1,370 m in vertical thickness, and the basalt at the bottom of the cores was dated from the Eocene at 51–59 million years before present. These drillings provided the necessary evidence in support of Darwin's subsidence theory leading to deep ocean atoll development. All material collected in the two deep Enewetak cores was limestone with numerous cavities, characteristic of shallow living reefs, and dominated by corals, coralline algae, mollusks, and foraminifera that grew and survived only in shallow water.

Since these species cannot survive below 50–100 m, they must have lived and calcified when they were in shallow waters, meaning that the volcanic foundations had experienced subsidence. Olivine basalts as well as those dredged up offshore on the deep slopes of Enewetak Atoll provide the physical proof that ancient oceanic volcanoes are the bases of atolls in the central Pacific. Additional tuff

**Enewetak Atoll, Marshall Islands, Figure 5** Aerial image of Runit Island and the Cactus and LaCrosse craters during and after the cleanup in 1978 and 2005 respectively: (a) Runit Island in 1978 along the northeastern rim of Enewetak Atoll and the two craters at the north end of the island during cleanup involving removal of contaminated soil and placement in Cactus crater (EG&G Electronics in Tipton and Meibaum 1981). (b) Runit Island in 2005 photo showing recovery of vegetation and the two craters at the northwest end of the island: Cactus, with the concrete dome (on the island) and LaCrosse (to north on ocean facing reef flat). A total of 17 of the 43 total nuclear tests at Enewetak were conducted on or within 2 miles of Runit Island (Google Earth, DigitalGlobe, Europa Technologies, and the National Aeronautical and Space Administration, 2009).

and volcanic glass deposits added further evidence that the volcano erupted at sea level after the Paleozoic, leading to the conclusion that the volcano reached sea level early in its growth and then later subsided to serve as the base for future reef growth, leading to the contemporary atoll of Enewetak. Numerous additional drillings were made at the atoll during the latter PACE program to reinforce and add to the earlier findings.

It is possible that coral settlement and fringing reef growth may have begun soon after basalt islands emerged in the Cretaceous or Eocene, lengthening the time when corals and other reef builders first established at an earlier age, and lengthening the process of biological evolution thereafter. The fossil corals retrieved and identified by John Wells from the Enewetak cores revealed 15 species and 3 genera that no longer exist. These species may have gone extinct or evolved into different species over time. Likewise, 21 species of fossil foraminifera and 3 fossil

species of sea urchins are also reported from the cores. In essence, the growth of the atoll reef over geological time has transcended the evolution of the reef builders that participated in its early construction.

### Biogeography and ecology

Extensive marine biological surveys were accomplished between 1947 and 1986 including dredge hauls, free diving, and hookah collections during the first decade and transitioning to scuba diving, remote operated vehicle surveys, and submersible dives during later surveys. More than 4,600 species of marine life have been collected and described from Enewetak (Table 2). These include more than 180 species of stony corals and more than 800 species of near shore fishes reported at Enewetak Atoll. Although the coral totals are higher than those reported at the smaller atolls at the north end of the archipelago, they are substantially lower than the 268 species of corals now reported at

**Enewetak Atoll, Marshall Islands, Table 2** Diversity levels of biota categories inventoried at Enewetak Atoll to 1987 (Compiled by Burch in Devaney et al., 1987)

| Taxa                                | # Species | # Genera | # Families | Sources in Devaney et al. (1987) |

Bikini Atoll to the east, and lower than species totals at Majuro and Arno atolls to the south. Most likely the high Bikini totals were due to substantially more survey and search effort (see “*Bikini Atoll, Marshall Islands*”). Coral species totals reported at the several largest islands of Palau, Yap, and Chuuk are also higher than at Enewetak but comparable to the Bikini levels. The Enewetak fish species totals are also much lower than those reported at Arno Atoll in the Marshall Islands, possibly due to greater rainfall and upwelling effects where the Equatorial Current meets the Equatorial Countercurrent. Moreover, certain groups of fishes common at Kwajalein Atoll are

**Enewetak Atoll, Marshall Islands, Figure 6** Robert Johannes on a reconnaissance visit at Enewetak Atoll before leading the Alpha-Helix Symbios study at Japtan Island in 1971. (Photo courtesy by James Maragos).

absent or rare at Enewetak. Contributing factors for the lower coral and fish levels may include geographic isolation of Enewetak from neighboring atolls, the reduced survey effort, and possibly the residual effects of the nuclear testing program.

The marine biological habitats and species at Enewetak Atoll are still among the most comprehensively studied in the world even though little research has been accomplished after 1985. Habitats surveyed in detail include:

- Deep lagoon biological communities
- Pinnacle and patch reefs of the deep lagoon
- Lagoon back reefs (or lagoon margins)
- Shallow passes on the perimeter reef between the northern islands
- Coralline algal ridges
- Ocean-facing fore reefs and
- Lagoon water column habitats

Other geological and ecological investigations have covered impacts of:

- Destructive storms on reefs
- Intertidal ecology
- Invertebrate coral predators (*Acanthaster*)
- Coral taxonomy
- Herbivory in sub-tidal communities
- Bioturbation in the deep lagoon including mobilization of radio-nuclides
- Fish communities, including shark assessments, fish reproduction, and recruitment
- Ciguatera fish poisoning and
- Biological communities in bomb craters and
- Upward reef growth and decline during the Pleistocene

**Enewetak Atoll, Marshall Islands, Figure 7** Coral specialists Michel Pichon (left), John Wells (center), and John Veron (right) at the Mid-Pacific Marine Laboratory-sponsored coral taxonomy workshop at Enewetak in 1976. The three specialists are deliberating over *Bikiniastrea laddi*, a coral first collected by geologist Harry Ladd at Bikini and described by John Wells. (Photo courtesy by James Maragos).

Some of the most important investigations included assessment of reef metabolism, trophic relationships, energy and materials flux, nutrient flux, calcification, and bioerosion rates of reefs by multidisciplinary teams including Odum and Odum (1955) and later (Figure 6; Johannes et al., 1972) during the Symbios/Alpha Helix expedition at Japtan Reef. In 1976, a coral reef taxonomy workshop was convened at Enewetak under the guidance of John Wells (Figure 7). Terrestrial environments have also been surveyed including soils, vegetation, reptiles, seabirds, shorebirds, insects, mammals, crustaceans, and other arthropods. Several islands along the southwest perimeter were also proposed as reserves and were in excellent health and mostly removed from the nuclear testing sites at the atoll.

### Summary and Conclusions

During a 40-year period, Enewetak served as World War II battleground, a U.S. nuclear testing proving ground, and an important atoll field station for marine scientists including geologists, biologists, and ecologists. The world's longest atoll drill cores were collected there and led to the confirmation of Darwin's subsidence theory on atoll evolution and documented the long history of living reefs among the world's largest and oldest atolls. However, the Enewetak people, who likely lived at the atoll for thousands of years, suffered greatly during the same time period and struggled against a world power to return home. Of all the questions left unanswered will be the fate of the people, the impact of the past nuclear testing on their atoll, and the uncertain future of both during the climate now beginning wash up on her shores.

Hopefully, scientists, governments, and islander residents alike will continue to cooperate and work towards a better understanding of the future while never forgetting the past. In one respect, the Enewetak people were able to return to their home atoll because it was not the first to be assaulted, and was larger and better able to withstand the impacts of the nuclear era vis-à-vis Bikini Atoll. In early 2009, Bikini was nominated for World Heritage as a cultural site for similar reasons that the Hiroshima Dome of Japan was recently inscribed – so that the World will never forget the role that her people and atoll played during the emerging nuclear age, the hardships they suffered, and the future lesson that such history should never be forgotten and repeated. The decision on the nomination will be made within a year. Perhaps soon Enewetak will be similarly recognized for its role and success in demonstrating how her people were able to return home and survive against great odds and serve as inspiration for others.

## ENGINEERING ON CORAL REEFS WITH EMPHASIS ON PACIFIC REEFS

---

James E. Maragos  
 U.S. Fish and Wildlife Service, Honolulu, HI, USA

### Definition

Engineering: design, planning, construction, and management of machinery, roads, causeways, buildings, bridges, docks, airfields, fortifications, waterways, power generation, water supply, waste discharge, etc.

### Introduction

The European renaissance and industrial revolution ushered in an era of unprecedented advances in, and global demand for, modern engineering and construction capability. Five centuries ago, European explorers traveled far from home, coming into contact with many coral reefs for the first time, and requiring engineering that focused

on improved means of navigation, transportation, safe overseas anchorages, and later on conquest, commerce, communications, and trade with many cultures in coral reef environments. By the mid nineteenth century, emphasis shifted toward resource exploitation and colonization of overseas continents and islands, including guano and phosphate extraction at many coral islands and atolls, and mining of valued ores and expansion of plantation agriculture and ranching at many larger tropical islands and sub-continents. By the mid twentieth century, engineering in coral reef environments focused on supporting modern global warfare, nuclear weapons testing, and civil works for emerging democratic states including construction of military bases, airfields and ports, urbanization, and reconstruction.

The consequence of these shifts was massive pollution and degradation of many coral reefs, especially during the past century. Only during the past half century has there been emphasis placed on minimizing the ecological impacts of engineering, coastal construction and related development. This chapter reviews past and present engineering on coral reefs and offers measures to reduce lingering effects and avoiding future environmental effects on Pacific coral reefs attributed to engineering and related construction.

### **Engineering and coastal construction requirements on coral reefs**

Generally, the four principal engineering categories on coral reefs have been: (1) dredging and excavation for navigation channels and turning basins for ships and boats; (2) discharge of fill to expand land, create airfields, harbors, and connect islands via causeways on especially smaller islands and atolls; (3) collecting or constructing armor rock for fortifying shorelines, harbor breakwaters, and onshore facilities; and (4) mining and quarrying reef blocks for concrete production and construction of buildings. The last category is covered in a companion section in the chapter on Infrastructure on Coral Reefs that includes additional case studies and expands the geographic scope of this review beyond Pacific reefs. The discharge or dumping of toxic and hazardous waste (hazmat) is beyond the scope of this review but which can result in adverse consequences to coral reefs. Assessment and remediation of hazmat sites are potentially dangerous and require specialists such as eco-toxicologists and industrial/environmental engineers at great cost. Hazmat sites can be avoided by prior planning and design that leads to proper construction, operations, and maintenance of facilities.

Coastal engineering on small Pacific low reef islands and atolls is especially needed because land areas and water supplies are limited and vulnerable to adverse seas and storm conditions. Coral rock is often very hard, especially on wave exposed reef crests which render it valuable for protecting shorelines, but its extraction often requires heavy equipment or use of explosives in zones of heavy surf that drives up the cost of the shore protection.

A common alternative to moving and placing large stones is using smaller, portable stones or rubble that can be carried by hand to fill up larger fish traps or wire-meshed cubes (gabions) previously placed on the shoreline. The rock-filled traps or gabions simulate the benefit of larger individual stones that better withstand movement and the erosive force of wave action and currents. Additional traps or gabions are later placed atop one another to create a seawall or sloping revetment along the shoreline. The advantages of this approach are that heavy equipment, blasting or quarrying of larger stone are not required. One disadvantage is that the wire meshing is not permanent and eventually corrodes, abrades or fails, reducing the structure to amorphous rock piles or ridges with reduced capacity to protect shorelines unless the wire mesh structures are routinely replaced. Furthermore, the shorelines where smaller stones and rubble are collected may be exposed to greater levels of erosion.

Improperly placed or designed shore protection structures of any kind eventually reverts back to shoreline erosion and the continuous need for more reef rock, rubble, and other forms of general purpose fill for repairs and haphazard shore protection. Continued excavation of coral sand and rock is also common at population and government centers in response to population immigration, especially from outer islands. As populations grow, additional coral rock and fill are needed for living areas, shore protection, dwellings, and road causeways connecting neighboring settlement islands on atolls. However, insufficient baseline studies and inadequate design have caused many road causeways to fail (Figure 1) or degrade adjacent reef areas (Figure 2) especially on atolls and barrier reefs.

WWII military bases on atolls also required road causeways to establish defensive perimeters, gun emplacements, shore protection, airfields, seaplane landing areas, protected harbors, and dredged navigation channels, if natural passes were absent. Inadequate width of channels, turning areas for ships, and aids to navigation at hastily constructed WWII-era harbors have also led to degraded reefs, many ship groundings, loss of fuel and supplies, loss of life, and the spread of alien and invasive marine and terrestrial species. Inadequate culverts or bridge openings in fill causeways connecting adjacent islands often led to shoreline erosion and failure of causeways at both military and civilian atolls and islands, disrupting land access and communications between adjacent islands. Many of these effects can be mitigated through proper engineering and related oceanographic assessment of wave energy, currents, and tidal fluctuations. Table 1 summarizes engineering activities, equipment, and construction purposes at coral reefs.

### **Adverse ecological consequences of poorly designed engineering activities and structures**

Serious direct effects to reefs can result from dredging, other forms of excavation, and discharge of fill on reefs to create land. Filling reefs to create land represents a permanent loss of the buried reefs as well as additional

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 1** Adverse consequences of poorly engineered causeways on coral reefs: (a) Reef flat before construction with wave action driving waters into the lagoon between islets. (b) Fill causeways connect islets but block flow and raise water levels. (c) High waves and seas breach causeways, preventing road access between islets. (d) Culverts or bridges in causeways maintain lower water levels, preventing causeway failures (all figures after Carpenter and Maragos, 1989; Maragos, 1993 except as otherwise indicated).

injury to reefs at the excavation/dredging sites and reefs adjacent to the fill areas. Fill areas not properly protected by filter cloth, revetments or seawalls may fail, releasing sediments, chemicals, and corroded metallic debris that are carried to healthy reefs, expanding the area of injury to healthy reefs. These types of impacts have been documented at French Frigate Shoals (Hawaii) and Palmyra Atoll (Line Islands). Limited sources of fill for residential areas and garbage landfills have degraded reefs and adjacent residential areas at Majuro Atoll and Ebeye Island (Marshall Islands) and Tarawa Atoll (Gilbert Islands). In one example at Kosrae Island, revetment stone and filter cloth was placed before discharge of fill material for an airfield that greatly reduced impacts to adjacent reefs (Figure 3). Designing shore protection structures on reefs often requires engineers to think beyond standard civil engineering practices and to consider options that reduce reef and operational impacts.

Road causeways constructed to connect the islands at southern Tarawa and islands north of Ebeye (Kwajalein Atoll, Marshall Islands) have breached with expensive repairs constantly required (Figure 1). Meanwhile the road causeways at these two atolls and at Palmyra have disrupted lagoon circulation, increased lagoon water temperatures, and caused shoreline erosion. Injury from WWII constructed road causeways at Palmyra are now degrading ocean reefs, and its lagoon reefs remain essentially dead even after 70 years since causeway construction (Figure 4). Road causeways at the larger volcanic islands of Kosrae Island, and Pou Bay at Weno Island (Chuuk, Caroline Islands) have also restricted water exchange in lagoons, blocked fish migrations, contaminated marine waters, and degraded reef areas. Installation of larger standard culverts at Pou Bay led to better water exchange and recovery of reef areas (Figure 5).

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 2** Adverse effects of causeway construction between Lelu and Kosrae islands: (a) Before causeway construction, fish runs, seagrass beds, a lagoon, a deep reef hole, and offshore reef habitats thrived and supported the main population center at Lelu Island. (b) After causeway construction, water exchange and fish runs deteriorated; confounding the problem was the haphazard construction of a second causeway for an airfield that blocked one of the two culverts of the main causeway, exacerbating pollution and sedimentation in the harbor. (c) The main culvert could be un-blocked and additional culverts installed to restore fish runs and the quality of coral reefs and seagrass habitats.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Table 1** Summary of engineering and construction techniques used on coral reefs (after Maragos, 1993)

Additional indirect adverse effects to adjacent reefs are often more severe when ship channels dredged through atoll perimeter reefs:

- Fine sediments are stirred up on lagoon floors
- Lagoon waters become stratified
- Reef crests are permanently exposed to air
- Lagoon and ocean reef habitats are degraded
- Water circulation between ocean and lagoon habitats is reduced (Figure 6)

Irreparable impacts to coral reefs have been documented at U.S. Navy installations constructed before and during WWII at several atolls and islands in the central Pacific: Pearl Harbor; French Frigate Shoals; Midway Atoll; Kāne'ohe Bay (Figure 7); Johnston Atoll; Palmyra Atoll; Kiritimati Atoll; Wake Atoll; and Kanton Atoll. Also, 1960 airfield constructed at Tutu'ila Island (American Samoa) blocked circulation at neighboring Pala Lagoon that killed corals, degraded water quality and mangroves, and caused shoreline erosion at nearby villages (Figure 8). Harbors not properly designed may also invite ship collisions and groundings as has also occurred at Pearl Harbor and Palmyra Atoll. The reefs of Baker Island (Phoenix Islands) have also been degraded at an anchorage where extensive war materiel was dumped and vessels scuttled immediately offshore before the troops left the island. Alternatively, harbors placed inland from the

shoreline reduce impacts to coral reefs at small boat and deep draft harbors in Hawaii (Figure 9).

Engineering and construction projects that do not address long-term trends and the indirect impacts of population growth and crowding on coral reef islands are also bound to fail. For example, the U.S. Army missile testing center at Kwajalein Atoll has not adequately addressed the impact of population growth at Ebeye stimulated by more than a thousand workers who commute daily to the neighboring military base at Kwajalein Island. In essence, Ebeye has become a "border town" outside the jurisdiction of the military base, but with the local government lacking long-range plans and funds for water supply, sanitation, garbage, and health care deficiencies at Ebeye. The reefs and resort areas on Maui and Waikiki (Hawaii) and Denarau (Vanua Levu, Fiji) have also suffered from myopic decision-making by government engineers and planners. Continuous beach replenishment is now required at Waikiki and seawalls have replaced the once beautiful beaches at Denarau because the hotels were allowed to be constructed too close to the ocean, putting them in harms way during high seas and storm conditions. An airfield placed offshore from Kuta Beach in Bali permanently destroyed much of the beach and could have been avoided by moving it behind the shoreline (Figure 10).

Maui (Hawaii) resorts and the local government needed better planning and support for an ocean outfall to

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 3** Mitigating the effects of dredging and filling to construct a reef runway and dock at Okat, Kosrae: (a) Okat supports the largest natural bay, seagrass beds, estuary, coral reefs and mangroves in Kosrae. (b) The original construction plan proposed cutter-head dredging to generate and stockpile fill material for the dock and airfield. However, the construction contractor was required to construct a free standing revetment around the perimeter of the airfield and install filter cloth to block discharge of dredged materials outside the airfield. The changed revetment design spared destruction of adjacent reefs and prevented undermining and failure of the airfield from strong wave-driven currents since its completion in 1980.

discharge treated sewage offshore and away from beaches and coral reefs near the resorts. Instead sewage is still discharged into groundwater via injection wells, resulting in higher nutrient concentrations that seep into the ocean

at the shoreline, resulting in prolific algae growths stimulated by the nutrients. In turn the algae smother offshore coral reefs and accumulate as drifts on the beaches that require constant collection and disposal to maintain

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 4** Adverse effects from Naval Air Station construction at Palmyra Atoll, U.S. Line Islands: (a) Before 1938 Palmyra Atoll and its 50 emerald islets was called the “Pearl of the Pacific.” (b) Before WWII the U.S. Navy dredged a channel through the perimeter reef, lowering lagoon water levels and cleared a seaplane landing area. The fill was used to connect the islets and construct road causeway around the perimeter of the atoll and expand land areas for a harbor and airfield. The construction immediately destroyed all reef life in East lagoon and eventually the entire lagoon. Later breaching of causeways and the synergistic effect of a coral bleaching event in 1997 degraded coral gardens west of the lagoon and now threaten coral gardens on eastern reefs. After 70 years there has been no reef recovery in the lagoon, although restoration plans are now being developed (Figure after Dawson, 1959).

aesthetics. Meanwhile the government and resorts continue to hire consultants to study and debate the dilemma.

Sewage discharges in the lagoon of Kāneʻohe Bay (Hawaii) in the 1960s resulted in decline of corals and proliferation of green algae stimulated by nutrients in the sewage that were overgrowing and smothering corals. After 1968–1972 ecological studies demonstrated the adverse effects of the sewage, government and community leaders agreed to move the sewage outfall to a deeper site outside the lagoon in 1977–1978 where wave energy dissipated and diluted the sewage and caused only minor effects to coral reefs (Figure 7). Subsequent lagoon surveys in 1983 and 1997 in the Bay revealed the recovery of coral and decline of the invasive green algae. Additional

surveys were accomplished in the Bay in 2009, revealing further declines in green algae but the rise of alien red algae (Nadiera Sukhraj, pers. comm.).

### Summary

- Planning teams should be assembled before engineering plans and specifications are approved and include engineers, scientists, planners, economists, and members of the affected communities.
- Governments should adopt and require Environmental Impact Assessment (EIA) procedures and coordination before decisions are made.
- The EIA process should include: public scoping of issues; baseline ecological, oceanographic and cultural

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 5** The fall and rise of the estuary and coral reefs in Pou Bay, Chuuk Lagoon from 1935–1980: (a) Before 1935 Pou bay was a productive estuary, mangrove forest, seagrass bed, and shellfish bed with adjacent villagers dependent on it for subsistence. (b) Then the Japanese built a road causeway across the mouth of the bay that polluted and degraded the ecosystem because culverts placed through the causeway were inadequate in size and number. (c) Mandated by U.S. environmental laws and regulation, reconstruction of the causeway required installation of larger culverts which in turn helped restore the bay's marine ecosystems by 1980.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 6** Adverse impact of boat and ship channels cut into lagoons lacking deep natural passes: (a) Numerous atolls lack adequate discharge from natural passes to match inflow from tides and wave action. Experiencing constant water flow, perimeter reef crests continue to grow upwards and lagoon water levels rise above adjacent ocean water levels at low tide. (b) Large or deep ship channels cut through perimeter reefs drains excess lagoon waters, exposes perimeter and lagoon reefs to the air, kills corals and other reef life, permanently modifies deep lagoon circulation, and perpetually stirs up fine, often colloidal, bottom sediments.

- surveys and analyses; evaluation of a full range of alternative sites and designs; and evaluation of a full range of measures to reduce or avoid adverse impacts.
- The final decisions of the EIA should be incorporated into the construction plans and specifications in the form of an Environmental Protection Plan that the construction contractor(s) must honor.
- The EIA process should require an environmental audit of the completed project to address impacts not covered or anticipated in the pre-project phase of the EIA.

- The project area should be monitored by an independent team of scientists and engineers who report construction violations or issues directly to the government contracting officer who in turn has the authority to suspend the construction until deficiencies are corrected.
- Use of explosives should include measures to reduce damage to adjacent reefs by (1) drilling holes to load smaller charges and (2) covering each detonation site with heavy cloth to reduce fly-rock, concussion and shock to marine life.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 7** Adverse planning of military construction and sewage discharge in Kaneohe Bay, Hawaii: (a) Before 1938, Kaneohe Bay was an undisturbed healthy ecosystem, supporting one of two barrier reefs in the Hawaiian Islands. (b) WWII military construction dredged a seaplane landing area and deep ship channels through the barrier reef and lagoon, and created fill land for the military base using dredged coral. (c) In the early 1960s sewage outfalls were placed in the south bay where water circulation was poor, causing pollution, killing corals, and stimulating algal overgrowth of corals in the lagoon. (d) Outfalls were moved outside the bay by 1978, resulting in coral recovery and decline of algal overgrowth by 1983, with the new outfall was placed in well-mixed ocean waters offshore where reefs were unaffected. Additional surveys through 2009 revealed the disappearance of the earlier algae and spread of new alien algae released in the bay by researchers that now threaten rare corals.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 8** Adverse consequences of poor planning and design of airfield construction on reefs: (a) Pala Lagoon in American Samoa before airfield construction was home to lagoon reefs, rare mangroves, and shellfish beds of importance to adjacent Nu'uuli villagers. (b) Fill for airfield construction was placed too close to the entrance of the lagoon, reducing circulation, creating lethal water temperatures, killing reef life, eroding nearby beaches, contaminating shellfish, and polluting waters near the village. (c) Had EIA procedures been required a decade earlier, an alternative of placing the airfield on land would have avoided all these impacts and reduced construction and maintenance cost.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 9** Port construction at Barbers Point, Hawaii designed to minimize impacts to coral reefs: (a) Before harbor construction in 1980, U.S. environmental laws and regulations required evaluation of a full range of alternatives. (b) The two major options were to construct the harbor offshore, or . . . . . (c) Quarry a harbor inshore of the existing shoreline. The latter option was selected, and all excavation in the new harbor basin, and channel dredging outside were completed before the barrier separating the two areas was removed to complete the harbor. This design minimized the footprint of the harbor on coral reefs and also prevented turbid waters from discharging to offshore reefs during most of the construction period. The project cost was also much less and generated fill material for future industrial and construction projects.

- Nations with coral reefs should design a coastal zone management (CZM) regime that (1) allows only projects and facilities that need to be placed in the coastal zone, and (2) establish greenbelts and other restricted zones to protect beaches, mangroves, and coral reefs and prevent resorts or other building development in

this restricted zone unless absolutely required. This measure alone would save many existing beaches and prevent proliferation of seawalls and groins to protect luxury housing and other structures that could have been sited elsewhere and out of harms way from storms, high waves, tsunamis, etc.

**Engineering on Coral Reefs with Emphasis on Pacific Reefs, Figure 10** Airport construction destroys Kuta Beach at Denpasar, Bali: (a) Kuta Beach in Denpasar, was Bali's most important tourism destination before 1967. (b) Requiring a modern airfield to support increasing tourism, the government opted to extend much of the runway offshore to minimize the high cost of purchasing land for the rest of the airport. After construction, the offshore end of the runway functioned as a giant groin that trapped sand flow from south to north along the beach, causing the north side of the beach to erode away, and destroying many adjacent residences and businesses. (c) Had the decision-makers consulted ocean engineers and scientists, they would have been aware of the beach impacts and the corresponding socio-economic costs of placing the runway in the beach. Instead they may have opted for the alternative of placing the entire runway well behind the beach.

- Dredging and filling methods and plans for projects should require reduction of turbidity and sedimentation or confining both to the immediate construction sites to protect adjacent reefs.
- Other mitigation methods should be evaluated such as coral transplantation that may also help reefs recover from previous impacts from sediments and dredging.

## EOLIANITE

Sue J. McLaren  
 University of Leicester, Leicester, UK

## Synonyms

Aeolianite (United Kingdom); Dunerock (South Africa); Grès dunaire (Mediterranean); Miliolite (India, Middle East); Kurkar (Israel)

## Definition

Eolianites are cemented sand dunes created by the processes of entrainment, transportation, and deposition on land, by wind. The accumulated dune sands are subsequently altered by various geochemical processes in a meteoric (freshwater) environment. Most eolianites have a high carbonate content, with clasts made up of whole/fragments of marine skeletons, *ooliths*, and peloids. Carbonate eolianites are commonly found in sub-tropical to tropical coastal locations. Silica- or lithic-dominated eolianites tend to be found in drylands or in more temperate environments. Most recognized eolianites in the landscape are Quaternary in age. Few examples of pre-Quaternary eolianites exist and this is thought to be due to misinterpretation of these deposits rather than to their absence from the stratigraphic record.

The grains making up siliciclastic eolianites are normally coarse silt to sand-sized, well-sorted, and rounded. In comparison, carbonate dunes contain a wider range of clast-size and -shape because the carbonate grains have a lower specific gravity (Frébourg et al., 2008) and some skeletal fragments are platy in nature, which enable larger clasts to be wind-entrained. Bedding structures include cross-bedding and laminations, which represent the progradation and extension of the dunes. Dune slipfaces are identifiable as steeply dipping laminae up to 30–34°. In terms of thickness, eolianites vary from <1 m to >100 m.

The mineralogical changes associated with the *diagenesis* of eolianites include the alteration of unstable high-Mg *calcite* and *aragonite* and precipitation of relatively stable low-Mg *calcite*. Dissolution of aragonitic shells and *ooids* often results in molds with fossil outlines preserved by micritic envelopes. Both air and water fill pore spaces in the vadose zone giving unevenly distributed cement patterns. Meniscus, rim, and pore-filling cements occur with crystal size normally ranging between 5 and 50 µm in diameter and crystal shape typically being bladed, equant, or syntaxial. Cement sources include dissolution of bioclasts, *ooids*, peloids, and carbonate-rich lithoclasts, terrigenous dust, seaspray, leaching of overlying sands, and precipitation from groundwater or overland flow (McLaren, 2007). Karstification or *palaeosols* may develop at/above major unconformities in eolianites and in semi-arid environments *calcretes* can develop because of processes of carbonate dissolution and rapid reprecipitation.

Relative *dating* techniques attempted to establish the age of dunes/eolianites include lithostratigraphy, human artefacts, and amino acid racemization. Of the numerical techniques, uranium-series *dating* on shells is problematic as they often behave as geochemically open systems. Radiocarbon *dating* requires organic matter to be present in the dunes and only dates back to ~50 ka. Luminescence *dating* of terrigenous grains has successfully obtained ages ranging from a few decades to several hundred thousand years.

## FAROES REEFS

---

Roger McLean  
School of Physical, Environmental and Mathematical  
Sciences, Canberra, ACT, Australia

### Synonyms

Basin reefs; Faros; Little ring-shaped reefs; Mini-atolls;  
Miniature atolls

*Faro* is a Maldivian name given to small atolls that rise in the lagoons of large composite atolls, or, are found on their rims (Agassiz, 1902). Despite his vast experience of coral reefs in the Pacific and Caribbean, Agassiz (Agassiz, Alexander (1835–1910)) said he had “seen nothing so striking” as “those remarkable rings which are so characteristic a feature in Maldivian coral reef scenery”. Classical faros are indeed striking, being perfectly circular reefs, usually less than 3 or 4 km in diameter surrounding a shallow secondary lagoon of depths generally less than 20 m. To J. S. Gardiner (Gardiner, John Stanley (1872–1946)) such reefs were technically “little atolls” but where a more precise term was necessary, he borrowed *faro* and *velu* from the Maldivian, the former signifying a small ring-shaped reef and the latter its central pond or basin.

Because faros rise from the lagoon floor and edges of atolls, their mode of formation must differ from oceanic atolls whose foundations extend to great ocean depths. And yet there has been no substantive study of faros in the *Maldives*, which contrary to popular belief do not occur throughout the archipelago but are restricted to the double chain of atolls in its central part, where there are several hundred faros. The occurrence of circular or oval faros within the lagoons appears to be related to two

factors: the presence of frequent or wide gaps or passes through the atoll rim; and, to the alternating northeast and southwest monsoons with reversals in swell and sea waves and locally generated wind waves. Faros developed on the peripheral rims themselves are rarely circular or even occluded. Rather they are often elongated parallel to the atoll edge, or are crescent- or horseshoe-shaped with the convex side facing the open sea.

A number of faro reefs are surmounted by islands, whose shape frequently mimics that of the parent reef. Some islands are restricted to parts of the reef rim, especially on faro with deep velu. In other cases, infill from sediments produced on the reef surface and transported into the velu results in centrally located, often circular islands (Kench et al., 2005).

While reefs that resemble Maldivian faros have been described from elsewhere including Indonesian waters, the northern Great Barrier Reef, and New Caledonia, the terms *faro* and *velu* should be limited to reefs in the Maldives. Moreover, faros *sensu strictu* are not to be confused with either micro atolls (*Microatoll*) or “oceanic faros”.

## FLORIDA KEYS

Barbara H. Lidz

U.S. Geological Survey, St. Petersburg, FL, USA

## Synonyms

Asymmetric reef-tract evolution; Calcified organisms; Cemented oolitic tidal bars; Cumulative coral reefs; Emergent reefal and oolitic limestone; Florida Keys National Marine Sanctuary; Holocene *Acropora palmata*; Inhabited island chain off south Florida; Key Largo Limestone; Miami Limestone; Outlier reefs; Pleistocene *Montastraea annularis*; Replicated antecedent facies and geomorphic landforms; Shallow south Florida shelf; Windward platform-margin rim

## Definitions

**Quaternary:** The Quaternary Period consists of the Pleistocene and Holocene Epochs, the most recent ages of geologic time. The Pleistocene ranged from ~1.8 Ma to 10 ka. The Holocene began at 10 ka and includes the present. On the basis of glacial/interglacial intervals as determined by oxygen-isotope analyses of fossil planktic foraminifera, the Quaternary has been divided into numbered Marine Isotope Stages (MISs). Even numbers represent glacial intervals: relative to the Florida Keys reef record, MIS 10, 8, 6, 4, and 2 are pertinent. Interglacial intervals are referred to as MIS 11, 9, 7, 5, 3, and 1, with MIS 1 being the present warm interlude. MIS 5 is subdivided into substages 5e through 5a. Coral ages show that Florida Keys reefs flourished during transgressive and regressive intervals immediately surrounding late Quaternary sea-level maxima at ~230 (MIS 7), 125 (MIS 5e), 112 (MIS 5d), 106 (MIS 5c), 92 (MIS 5b), and 80 ka (MIS 5a) (Muhs, 2002; Lidz et al., 2007). The highest stand among those maxima occurred at ~125 ka when the sea level was ~10.6 m higher than at present. Conditions then produced the now emergent fossil coral reef (Key Largo Limestone; Multer et al., 2002) and tidal-bar

oolite (Miami Limestone; Hoffmeister et al., 1967), which comprise islands of the Florida Keys.

**Q Units:** Quaternary marine sequences in the Florida Key Largo Limestone have been divided into Q1 (oldest) through Q5 (youngest) Units (Perkins, 1977). The first flourishing reef occurs in the Q3 Unit. The oldest Q3 corals (*Montastraea annularis*), cored in the upper Keys, have been dated to ~370 and 366 ka (Multer et al., 2002). Those authors and others (e.g., Muhs et al., 2003) correlate those ages to the highstand of MIS 9. However, some authors (e.g., Droxler et al., 2003a) argue that the Q3 reef could belong to MIS 11. The MIS 11 highstand was the highest (~20–25 m higher than at present) and longest (30–40 kyr duration) in the Quaternary (see papers in Droxler et al., 2003b).

**Mangrove peat:** Modern mangrove forests and calm water rim the Florida Keys. The forests form peat, a compacted accumulation of partially decomposed organic debris. Dates on and depths of Holocene peat recovered from beneath offshore coral reefs provide times of peat formation and positions of paleoshorelines relative to the present sea level. Peat presence implies quiescent conditions at those sites during formation. Higher elevation outer-shelf bedrock topography protected those sites from waves as sea level rose. The deepest Keys mangrove peat cored was recovered from ~15 m below the present sea level (Lidz et al., 1985).

**Bedrock:** Researchers regard the uneven Pleistocene limestone surface on the south Florida shelf as “bedrock.” Wherever bedrock in contact with overlying Holocene coral reefs and sands has been dated, the dates point to the highstand of 80 ka (Lidz, 2006).

**Ooids/oolite:** Ooids are concentric grains of calcium carbonate that precipitate in warm, highly agitated seawater. During the 125-ka highstand when the Key Largo Limestone reef was growing, seaward-flowing platform-interior waters piled up behind the reef, causing high-energy convergence zones around its northeastern and southwestern ends. Ooids formed in these zones and amassed as unstable tidal bars. With sea withdrawal, the exposed bars became cemented into (Miami Limestone) oolite.

## Geographic and geomorphic setting

The Florida Peninsula, located at the southeast corner of the continental United States, is the emergent part of a broad, shallow, southward-extending carbonate platform. Seawater (Gulf of Mexico, Straits of Florida, Atlantic Ocean) surrounds the peninsula to the west, south, and east (Figure 1). The Florida Keys form a discontinuous island chain trending west–southwest from the southern peninsular tip. The submerged bedrock ~5–7 km seaward of the Keys is Pleistocene, generally <12 m deep (Enos and Perkins, 1977), and harbors the largest coral reef ecosystem in the contiguous United States. Several meters deeper to the southwest than northeast, the shelf curves westward into the Gulf of Mexico where its shallow

**Florida Keys, Figure 1** Enhanced Thematic Mapper Plus image, acquired in May 2000 from the Landsat 7 satellite, shows the four geographic components of the South Florida Ecosystem: the Everglades (south part), Florida Bay, the Florida Keys, and the reef tract. Note anastomosing shallow-water mud banks in Florida Bay. Endangered mangroves fringe every visible shoreline. The upper and middle Florida Keys are an emergent 125-ka coral reef. The lower Keys are emergent ooid tidal bars of the same age. Seaward of the keys lie habitats of the inner shelf, Hawk Channel, sands, and Holocene reefs on the shallow outer shelf, and 30-m-high 80-ka fossil reefs at the shelf edge. The Gulf of Mexico is at left, Straits of Florida at right. Pre-existing topography and fluctuations in sea level were the primary controls on coral reef evolution and distribution.

depths terminate at the west end of a bedrock ridge known as the Marquesas–Quicksands ridge (Figure 2a). Farther west, the shelf underlies Holocene reefs and islands of the Dry Tortugas. Holocene flooding from southwest to northeast produced older reefs to the southwest. Most Keys reefs occupy water depths of ~3–30 m.

Bedrock topography controls major geomorphic elements: a depression under Florida Bay, the Florida Keys, an inner shelf, a depression beneath Hawk Channel, an outer shelf, and an upper-slope terrace in 40 m of water (Lidz et al., 2006). All parallel the margin, marked by the 30-m depth contour. Orientation, composition, and tidal-pass width divide the island chain into lower, middle, and upper Keys (Figure 2b). Modern reefs, located seaward of the Keys, are healthiest off the upper Keys, which lack natural tidal passes. The least healthy occur off the middle Keys where passes are numerous and wide (Lidz and Hallock, 2000).

The curved Florida Keys shelf is a windward platform margin. Prevailing southeasterly winds and waves are onshore in the northeast. Shallower water and lack of tidal passes limit influence of tides and currents. Daily sediment movement is negligible. Prevailing energy is along-shore in the southwest. Deeper open-marine conditions

and wide tidal passes permit strong tidal and current exchange between the Gulf of Mexico and Florida Straits. Sediment is transported offshelf.

### Seven coral ecosystems and reef decline

Excluding corals of the Q3 Unit, about which little is conclusively known, the past 325 kyr of Florida reef evolution are well studied (cf., Lidz et al., 2008). Seismic surveys, coring, sclerochronology, and radiometric dating of coral, mangrove peat, and calcrete have shown that the two most important controls on reefs during that time were fluctuating sea level and antecedent bedrock topography (Shinn et al., 1977).

Dates on Florida Keys corals record six late Pleistocene highstands and reef ecosystems. The two highest occurred at ~125 and 80 ka. The seventh (Holocene transgression) produced the modern ecosystem. Geomorphogenetic models derived from coral dates and seismic data show the origin and changing evolution of landforms at four dissimilar sites (reef and non-reef) along the shelf edge (Lidz, 2004). The models illustrate asymmetric evolution. The seven ecosystems accrued mainly by successive stacking of new coral

**Florida Keys, Figure 2** (a) Index map of south Florida and the Florida Keys. *Dashed red dogleg line* separates areas of Pleistocene ooid bank (Miami Limestone) of the lower Keys and coral reef (Key Largo Limestone) of the westernmost middle Keys. An ooid bank also formed at the east end of the reef and today underlies the city of Miami. Note that major tidal passes are in the middle Keys. *Dotted line* (30-m depth contour) marks the shelf margin, which lies within the Florida Keys National Marine Sanctuary boundary (blue line). Figure 1a is cited in figure captions for Chapters Calcrete/Caliche, and Porosity Variability in Limestone Sequences. (b) Schematic cross section (not to scale) illustrates geomorphic features across the south Florida shelf.

generations on top of older skeletal generations. The models also show backstepping (landward coral growth) and lateral stacking (linking) of reef tracts by infilling of broad backreef troughs (Figure 3a and b). Offbank sediment accumulations extended non-reef areas seaward over lesser distances.

Coral ages indicate that the proto-Florida platform was subaerially exposed from the post-125-ka regression to ~7 ka. Though the 80-ka highstand was the last that enabled Pleistocene marine deposition on the shelf, position of the sea then only reached a maximum of ~9 m below present (Lidz, 2006). Present depths to bedrock are <9 m on most of the shelf seaward of the Keys and average ~6–8 m on the Marquesas–Quicksands ridge. Thus, the platform interior and westward-extending ridge remained dry land for ~115 kyr. During that time, the landmass promontory protected five shelf-edge reef tracts from the cold Gulf of Mexico waters (Figure 4a and b). Coastal Florida Bay waters did not exist. Geomorphic settings of the post-125-ka Pleistocene highstands provided shelf-edge accommodation space, shelter, and favorable conditions for reef calcification and accretion. Relative to the long landmass duration, the collective time of off-shore Pleistocene reef accrual was comparatively short (~20 ka; Lidz, 2006).

For unknown reasons, the Holocene transgression produced only ~2 m of coral growth on the five 80-ka shelf-edge reef tracts before the rising sea fully inundated the shelf. As the sea rose, it created and gradually submerged ephemeral islands of mangrove/mud, coral rock, and sand. At ~4 ka, seawater was far enough inland to infiltrate inter-reef paleochannels of the Key Largo Limestone, creating tidal passes that would allow saltwater access to the Florida Bay depression. During these events, outer-shelf reefs (e.g., Grecian Rocks) behind the shelf-edge reef responded by backstepping landward to keep pace with the rise (Neumann and Macintyre, 1985). Though initiated on hard substrate, some reefs also backstepped over carbonate sand and rubble (e.g., Looe Key Reef; Shinn, 1980; Lidz et al., 1985).

Then conditions changed. At ~2 ka, coastal bay and cold gulf waters began to flow seaward through the passes, impacting health of reefs opposite the passes (Porter and Porter, 2002). Terrestrial and atmospheric stressors (Jameson et al., 2002), including African dust (Shinn et al., 2000), joined the assault. Corals responded by declining, then by succumbing rapidly within the last 30 years. As of this writing (October 2008), more than 95% of Florida Keys reefs are senescent (non-accretionary), coral mortality having resulted mainly from diseases. Only small, isolated colonies of reef-building coral species are alive. Reef-framework structure is decaying due to bioerosion, ocean acidification, and natural (hurricanes) and anthropogenic (boat groundings) mechanical breakdown. Where live corals exist, underlying skeletal framework is mostly overgrown by sea fans, sea whips, algae, fleshy encrusting organisms, sponges, and stinging corals, all associated with reefs in decline.

## Two structural architectures

Florida Keys reefs consist of two repetitive architectures: a narrow low-relief outer-shelf ridge-and-swale geometry (Figure 5) and a broad high-relief shelf-edge reef-and-trough geometry (Figure 4a and b). Both are linear, discontinuous, and submerged and parallel the curved shelf edge. Cores from transects across the outer-shelf rock ridges have recovered skeletal Holocene corals overlying Pleistocene corals (Shinn et al., 1977). Cored swales contain unconsolidated Holocene sands overlying a calcrete-coated subaerial-exposure surface that caps cemented Pleistocene sands. Eight such coral ridges are visible in aerial photographs (Lidz et al., 2007). The ridge-and-swale structure is tens of meters wide and thin relative to the reefs and troughs.

The five major shelf-edge tracts form the reef-and-trough structure on a wide (~2.5 km) upper-slope terrace ~40 m below the present sea level. The landward tract is the shelf margin. The others are outlier reefs, so called because empty backreef troughs render them detached from the shelf (Lidz et al., 1991). The exposed landmass promontory protected these five tracts so well for so long that they accumulated imposing relief (~30 m). Their corals date to ~106, 94–90, and 86–77.8 ka with an inferred age of ~127 ka at their bases. Thin Holocene reefs with spurs and grooves cap these reefs. The reef-and-trough geometry is hundreds of meters wide.

## Four coral nuclei

Pleistocene outer-shelf beach dunes, antecedent reefs, and a nearshore coral-and-oolite rock ledge are well-known coral substrates along the Florida reef tract. Ledge patch reefs, usually individual live head corals surrounded by sand halos, are in the shallowest of Keys reef settings (~3 m deep).
